# Advancing Profile-Based Curl-and-Warp Analysis Using LTPP Profile Data 

## FOREWORD

This report is focused on predicting and quantifying curling and warping of jointed portland cement concrete pavements. Researchers used the comprehensive research-quality datasets available through the Long-Term Pavement Performance (LTPP) program, supplemented by additional datasets collected by other Federal Highway Administration studies. The analyzed test sections are part of either the Specific Pavement Studies-2 or General Pavement Studies-3 LTPP experiments.

Researchers assessed the impact of curl and warp on fluctuations of the International Roughness Index (IRI); generalized relationships between the IRI and pseudostrain gradient (PSG) to less robust datasets (i.e., datasets typically available to State highway agencies); correlated PSG values to environmental factors, falling weight deflectometer results, and measured roughness; and examined the implications of short- and long-term changes in IRI in the appearance of areas of localized roughness. This report is intended for highway pavement engineers and researchers involved in performance analysis of concrete pavements.

Jean A. Nehme, Ph.D., P.E.<br>Director, Office of Infrastructure<br>Research and Development

## Notice

This document is disseminated under the sponsorship of the U.S. Department of Transportation (USDOT) in the interest of information exchange. The U.S. Government assumes no liability for the use of the information contained in this document.

The U.S. Government does not endorse products or manufacturers. Trademarks or manufacturers' names appear in this report only because they are considered essential to the objective of the document.

## Quality Assurance Statement

The Federal Highway Administration (FHWA) provides high-quality information to serve Government, industry, and the public in a manner that promotes public understanding. Standards and policies are used to ensure and maximize the quality, objectivity, utility, and integrity of its information. FHWA periodically reviews quality issues and adjusts its programs and processes to ensure continuous quality improvement.

| 16. Abstract <br> This report is focused on predicting and quantifying curling and warping of jointed portland cement concrete pavements. Researchers used the comprehensive research-quality datasets available through the Long-Term Pavement Performance (LTPP) program, supplemented by additional datasets collected by other Federal Highway Administration studies. The analyzed test sections are part of either the Specific Pavement Studies-2 or General Pavement Studies-3 LTPP experiments. Researchers assessed the impact of curl and warp on fluctuations of the International Roughness Index (IRI); generalized IRI and pseudostrain gradient (PSG) relationships to less-robust datasets (i.e., datasets typically available to State highway agencies); correlated PSG to environmental factors, falling weight deflectometer results, and measured roughness; and examined the implications of short- and long-term changes in IRI in the appearance of areas of localized roughness. Researchers also completed a literature review describing work on profile-based estimates of curl and warp and the influence of curl and warp on the IRI. Theoretical and analytical modeling showed that the original hypothesis of a direct relationship between PSG and IRI was valid, but that the assumption of a linear relationship was incorrect. Researchers proposed an alternative model that produced a high correlation between IRI and PSG on field data with diurnal and seasonal changes in curl and warp. |  |  |  |

## LIST OF SYMBOLS

| $b$ | slab length |
| :---: | :---: |
| $c_{\lambda}$ | cosine of $\lambda$ |
| chr | hyperbolic cosine of $\lambda$ |
| curvature $_{n}$ | Three-point estimate of curvature at point n |
| $d_{0}$ | deflection measured at the center of the load plate |
| $d_{0}^{*}$ | nondimensional deflection coefficient at the center of the load plate |
| $d_{x}$ | peak deflection in inches at sensor offset |
| $h$ | slab thickness |
| $h_{B}$ | average layer thickness of base |
| $h_{G B}$ | average layer thickness of GB |
| $h_{G S}$ | average layer thickness of granular subbase |
| $h_{L C B}$ | average layer thickness of LCB |
| $h_{\text {PATB }}$ | average layer thickness of PATB |
| $h_{P C}$ | average layer thickness of PCC |
| $h_{T S}$ | average layer thickness of treated subbase |
| $k$ | modulus of subgrade reaction |
| $k_{\text {est }}$ | estimated modulus of subgrade reaction |
| $l$ | radius of relative stiffness |
| $l_{\text {est }}$ | estimated radius of relative stiffness |
| $s \lambda$ | sine of $\lambda$ |
| shı | hyperbolic sine of $\lambda$ |
| slope $_{n}$ | two-point estimate of slope at point $n$ |
| $x$ | distance along the slab relative to the slab center |
| $y(x)$ | fitted displacement profile |
| $z$ | vertical deformation |
| $z_{0}$ | uplift at slab ends |
| $A$ | adjustment factor for nonrandom roughness |
| $A F_{d_{0}}$ | adjustment factor for $d_{0}$ |
| $A F_{l e s t}$ | adjustment factor for $l_{\text {est }}$ |
| $\mathrm{AREA}_{7}$ | deflection basin parameter for the seven-sensor configuration |
| $D I_{J 1}$ | deflection intercept at the slab center |
| $D I^{\prime 2}$ | deflection intercept at the slab corner |
| E | elastic modulus of the PCC slab |
| $F$ | estimated PCC flexural strength |
| $H_{0}$ | average relative humidity in the first month after construction |
| $H_{1}$ | average relative humidity in the first 10 years after construction |
| IRI $_{\text {Back }}$ | superimposed background roughness. |
| $I_{\text {IR }}^{\text {Comb }}$ | IRI of the combined profile |
| IRI $_{\text {Curl }}$ | IRI of the synthetic profile of curl and warp |
| $L$ | square slab size |
| $L_{\text {slab }}$ | average slab length |
| $L_{S}$ | section length |
| $L T E_{i}$ | LTE intercept using data from the first 10 years after construction |

| $L^{\prime}$ E $_{s}$ | LTE slope using data from the first 10 years after construction |
| :---: | :---: |
| $N$ | number of points in the roughness profile |
| $N_{E}$ | index of the last value above the threshold for the area of localized roughness |
| $N_{S}$ | index of the first value above the threshold for the area of localized roughness |
| $P$ | load magnitude |
| $P S G_{i}$ | initial PSG value after construction |
| $P S G_{s}$ | rate of change in PSG value after construction |
| PV | estimated PCC paste volume |
| $R_{i}$ | roughness profile at point $i$ |
| $R_{E, i}$ | sum of the ER at point $i$ in the profile |
| $R_{T}$ | roughness threshold |
| $T_{0}$ | average temperature in the first month after construction |
| $T_{1}$ | average temperature in the first 10 years after construction |
| $W_{\text {slab }}$ | average slab width |
| $\alpha \Delta T / h$ | temperature gradient |
| $\kappa$ | curvature |
| $\lambda$ | nondimensional trigonometric and hyperbolic function argument |
| $\mu$ | Poisson's ratio |
| $\Delta_{H 0}$ | average difference between the maximum and minimum daily relative humidity in the first month after construction |
| $\Delta_{H 1}$ | average difference between the maximum and minimum daily relative humidity in the first 10 years after construction |
| $\Delta_{T 0}$ | average difference between the maximum and minimum daily temperature in the first month after construction |
| $\Delta_{T 1}$ | average difference between the maximum and minimum daily temperature in the first 10 years after construction |
| $\Delta x$ | profile sample spacing, profile recording interval |
| $\Delta z$ | relative uplift |
| $\Delta D I$ | difference between deflection intercept at the slab center and the slab center |
| $\Delta D I_{i}$ | $\Delta D I$ intercept |
| $\Delta D I_{s}$ | $\triangle D I$ slope |
| $\Delta T$ | temperature gradient |
| $\Delta \varepsilon_{s h} / h$ | moisture gradient |

## CHAPTER 1. INTRODUCTION

This study applied profile-based curl-and-warp analysis to longitudinal profile data from jointed plain concrete pavement (JPCP) test sections within the Long-Term Pavement Performance (LTPP) program. The LTPP program was initiated in 1986 by the Strategic Highway Research Program to collect high-quality performance data for various pavement experiments under varying traffic and environmental conditions. LTPP experiments include General Pavement Studies (GPS) and Specific Pavement Studies (SPS). GPS experiments are divided into types of pavement, including JPCP, which is designated as GPS-3. SPS experiments have multiple test sections per project, and each test section has unique structural factors. SPS-2 projects include JPCP test sections with 12 core test sections and several agency-specified supplemental sections. The core test sections have a unique combination of structural factors as defined by the SPS-2 experimental design and research plan. ${ }^{(1)}$ Supplemental sections typically have unique design properties specified by the local agency. LTPP data have been used to demonstrate the behavior of pavements regarding environmental factors, structural design, and construction practices.

The Federal Highway Administration (FHWA) report, Curl and Warp Analysis of the LTPP SPS-2 Site in Arizona (FHWA-HRT-12-068), proposed a method for estimating curl and warp of jointed portland cement concrete (PCC) pavements using the longitudinal profile. ${ }^{(2)}$ The report showed that fluctuations in the measured profile caused by curl and warp, as well as the long-term changes in the profile caused by warp, exhibited a strong statistical correlation to changes in the International Roughness Index (IRI). Consequently, the method for estimating curl and warp of jointed PCC pavements using the longitudinal profile provided a technique to separate roughness associated with curl and warp from long-term changes in roughness caused by other factors. For the low-strength sections within the Arizona LTPP SPS-2 site, this method provided a much clearer view of the structural and functional status throughout the monitoring history than the IRI alone.

The method quantified curl and warp using a pseudostrain gradient (PSG). ${ }^{(3)}$ Researchers assigned PSG values to individual slabs by fitting their measured slab profiles to the profiles produced using the Westergaard solution for determining slab deformation using pavement structural properties. The PSG represents the linear strain gradient required to deform the slab into the measured shape. The average PSG value for all slabs within a test section summarized curl and warp for each profile measurement. The method established site-specific linear relationships between changes in IRI and changes in average PSG using profile measurements from multiple monitoring visits.

The method was successful on the Arizona LTPP SPS-2 site. ${ }^{(2)}$ The method's application, however, required profile measurements on the site over several seasonal and diurnal cycles. The quality of the statistical relationship between PSG and IRI depended on observing large changes in PSG, and a different relationship between IRI and PSG was observed on each test section.

This research applied the PSG-based curl-and-warp analysis to a wider range of LTPP test sections over a more diverse range of climates in support of three lines of investigation, which include the following:

1. Advancement of the profile analysis algorithms and statistical procedures from FHWA-HRT-12-068. ${ }^{(2)}$
2. Application of the PSG method to investigations of the curl-and-warp phenomena related to structural behavior.
3. Examination of the effect of curl and warp on areas of localized roughness (ALRs).

Each line of investigation depended on a large volume of profile analysis results. This report describes major tasks and analyses performed in support of the research; additional details are presented in the appendices. Chapter 11 provides key findings and recommendations across all elements of the study.

## PROFILE ANALYSIS ALGORITHMS

The project team selected five SPS-2 sites and five GPS-3 test sections for analysis based on geographic distribution, life span, and available seasonal data. Chapter 2 describes the SPS-2 and GPS-3 test sections for analysis. Appendix B provides a detailed list of design features and profile-measurement history for each test section.

The research team created a rigorously synchronized profile dataset for iterative and efficient application of the curl-and-warp algorithm. The process for data-quality screening and synchronization ensured consistent placement of joint locations for all profile measurements throughout the monitoring of each test section. Chapter 4 summarizes each stage of the profile data preparation and analysis, including synchronization, data-quality screening, roughnessindex calculation, joint finding, and PSG calculation. Appendix A describes a literature review that revisited key references pertaining to estimates of curl and warp based on changes in surface profile and the influence of curl and warp on the IRI. Appendices C through H describe the calculation algorithms and present the outputs of the analyses in detail.

Advancing the profile analysis algorithms and statistical procedures included demonstrations of using PSG to examine curl-and-warp behavior. Chapter 5 demonstrates methods of using PSG to examine changes with time, spatial variations, and differences in behavior among test sections. Advancement of the curl-and-warp analysis also included a detailed examination of the relationship between IRI and PSG for the 83 PCC test sections selected for this study. The linear relationship proposed in FHWA-HRT-12-068 did not adequately describe the relationship between IRI and PSG for the broader dataset used in this research. As such, researchers developed an alternative. Chapter 6 proposes an empirical model that relates IRI and PSG based on theoretical numerical simulation, and chapter 7 presents results from the application of the model to the measured profile data.

## INVESTIGATIONS OF STRUCTURAL BEHAVIOR

The investigations related to structural behavior and the profile-based analyses are interrelated because the procedure for estimating PSG requires estimates of pavement structural properties as inputs. Investigations of the curl-and-warp phenomena included correlation to environmental factors and falling weight deflectometer (FWD) results for which PSG estimates functioned as an independent variable. The following research tasks are described in chapters 3,8 , and 9 , respectively:

- Estimation of structural factors: structural factors that are required for the calculation of the PSG include layer thicknesses, Poisson's ratio, the elastic modulus of the PCC, and the modulus of subgrade reaction or the composite reaction of base and subgrade layers. These moduli of subgrade reaction, however, were measured from remolding soil samples, which may not accurately represent in-situ conditions. This task, therefore, employed an algorithm provided in AASHTO Guide for Design of Pavement Structures, (circa 1993) published by American Association of State Highway and Transportation Officials (AASHTO), which combined the given moduli for each layer into a single composite modulus. ${ }^{(4)}$ Additionally, backcalculation results from Long-Term Pavement Performance Program Determination of In-Place Elastic Layer Modulus:
Backcalculation Methodology and Procedures (FHWA-HRT-15-036) were available and FWD data were used to backcalculate modulus values. ${ }^{(5)}$ Researchers collected information from these multiple sources and selected the values that represented these variables to be used in the estimation of structural factors.
- Correlation of curl and warp to environmental factors: PSG derived from the profile quantified the level of curvature present in pavement slabs but did not directly imply a climatic cause. The PSG values were correlated to environmental factors to evaluate the effects of climatic factors on pavement curl and warp. Typically, curling is considered a response to differential thermal expansion caused by a temperature gradient. Alternatively, warping is considered the result of differential drying shrinkage resulting from a moisture gradient. This analysis examined the correlation of PSG to available environmental measurements that affect curl, such as temperature gradient, average temperature, and average relative humidity. Detailed results and models produced in this task are provided in appendix I.
- FWD analyses: deflection measurements from FWD testing have the potential to indicate the amount of deflection from curling of pavement. Typically, there is a linear relationship between the load applied at the plate and the deflection of the pavement under the plate. This linear elastic relationship was modeled using deflection measurements at three load levels used in LTPP FWD testing. Linear regression showed that the intercept value typically was not zero, implying an initial deflection was present in the slab prior to loading. This intercept value indicated the presence of uplift in the PCC pavement from curling. FWD analysis explored the relationship between deflection intercept (DI) from FWD testing and PSG values from profile-processing methods. The analysis also compared the relationship between load-transfer efficiency (LTE) and PSG values.

## ALR

The analyses described in chapters 5 through 7 demonstrated short- and long-term changes in average IRI values due to curl and warp, as well as long-term changes in roughness caused by other factors. Chapter 10 examines the implications of those changes to the appearance of ALR. The study proposes several methods of quantifying and displaying changes in ALR in terms of location, length, and severity. These methods are used to demonstrate the effect of curl and warp on short- and long-term changes in ALR, persistence and growth of ALR that appears early in the service life of pavement sections, and repeatability of placement and severity of ALR among multiple profile-measurement passes. Appendix J provides a detailed background and analysis of the results.

## CHAPTER 2. TEST SECTIONS

Researchers performed the profile measurements analysis on five SPS-2 test sites and five GPS-3 test sections.

Table 1 lists the SPS- 2 sites used in this study. SPS-2 sites were selected based on long-term, consistent monitoring of profiles within the LTPP program; diversity of climate; and availability of additional seasonal and diurnal profile measurements from a previous curl-and-warp study performed by FHWA. ${ }^{(6)}$

Table 1. SPS-2 sites.

| State | Climate | Test <br> Sections | Monitoring <br> Duration <br> (Years) | Profile- <br> Measurement <br> Visits | Additional FHWA <br> Visits |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Arizona | DNF | 21 | 22 | 23 | Seasonal, diurnal |
| Kansas | DF | 13 | 23 | 24 | Seasonal, diurnal |
| North Carolina | WNF | 14 | 21 | 30 | Diurnal |
| Ohio | WF | 19 | 18 | 21 | Seasonal, diurnal |
| Washington | DF | 13 | 20 | 21 | Diurnal |

$\mathrm{DNF}=\mathrm{dry} / \mathrm{no}$ freeze; $\mathrm{DF}=$ dry freeze; $\mathrm{WNF}=$ wet/no freeze; $\mathrm{WF}=$ wet/freeze.
Table 1 provides the number of test sections at each site. Each site includes 12 core test sections with variations in slab thickness, PCC flexural strength, base design, and slab width that contribute to a broader factorial matrix for the LTPP SPS-2 experiment. ${ }^{(7)}$ Each site also includes supplemental test sections selected by State departments of transportation (DOTs) for comparison to a standard local design or to augment the core matrix.

One site from each of the LTPP climate zones was included. The climate at each site was verified using average monthly rainfall and temperature from the LTPP database. The Kansas site experienced more rainfall than expected for the dry/freeze region.

Table 1 lists total monitoring duration in years and the number of LTPP profile-measurement visits to each site included in this study. Many of the sites were in service when the analysis was completed and were monitored beyond the duration included in this research. The profile measurements at the sites in North Carolina, Ohio, and Washington included three visits over a 24-hour cycle in 2014. Monitoring the North Carolina site included seasonal visits over three annual cycles starting in fall 1997, fall 1999, and fall 2000.

In addition to LTPP profile measurements, the analysis for this study incorporated profile measurements from another FHWA curl-and-warp study. ${ }^{(6)}$ FHWA profile data included diurnal measurements of all five sites listed in table 1 and seasonal measurements of three sites. Diurnal measurements occurred before sunrise, after sunrise, at midafternoon, and after sunset over a single 24 -hour cycle. Seasonal measurements occurred once per season over a 1-year cycle, and each seasonal measurement visit included measurements over a diurnal cycle.

Table 2 lists the sections from the seasonal monitoring program (SMP). Additional profile-measurement visits were available from each section. For example, the 38 additional visits to Arizona section 040215 included 19 cases when the section was visited twice in the same day. Thirty-four additional visits to North Carolina section 370201 formed 18 daily groups and completed seasonal measurement cycles from fall 2001 through summer 2003. The 18 daily groups include 11 pairs of visits from the same day and 7 instances when the section was visited 3 times on the same day. The 15 additional visits to section 390204 completed seasonal measurement cycles from winter 1997 through fall 2000.

Table 2. Seasonal monitoring sections.

| State | Section | Additional Visits | Daily Groups |
| :---: | :---: | :---: | :---: |
| Arizona | 040215 | 38 | 19 |
| North Carolina | 370201 | 34 | 18 |
| North Carolina | 370205 | 4 | 3 |
| North Carolina | 370208 | 3 | 2 |
| North Carolina | 370212 | 2 | 1 |
| Ohio | 390204 | 15 | 7 |

Table 3 lists the GPS-3 test sections. The five GPS-3 sections listed offered geographic diversity, consistent long-term monitoring of profile within the LTPP program, and seasonal and diurnal monitoring within the FHWA study of curl and warp. Sections 063021, 133019, 183002, and 493011 were included in the SMP.

Table 3. GPS-3 sections.

| State | Section | Climate | Monitoring <br> Duration <br> (Years) | Profile- <br> Measurement <br> Visits | Additional FHWA <br> Visits |
| :---: | :---: | :---: | :---: | :---: | :---: |
| California | 063021 | DNF | 25 | 21 | Seasonal, diurnal |
| Georgia | 133019 | WNF | 24 | 39 | Seasonal, diurnal |
| Indiana | 183002 | WF | 25 | 31 | Diurnal |
| Minnesota | 273003 | WF | 18 | 12 | Seasonal, diurnal |
| Utah | 493011 | DF | 26 | 31 | Seasonal, diurnal |

$\mathrm{DNF}=\mathrm{dry} / \mathrm{no}$ freeze; $\mathrm{DF}=$ dry freeze; $\mathrm{WNF}=\mathrm{wet} / \mathrm{no}$ freeze; $\mathrm{WF}=\mathrm{wet} /$ freeze.
Thirty-nine visits to section 133019 included seasonal visits over 4 annual cycles starting in spring 1992, starting in winter 1996, starting in fall 1997, and starting in spring 2000. Visits were made in 11 pairs, meaning that 2 visits were performed at different times on the same day. Thirty-one visits to section 183002 included seasonal visits over 1 annual cycle starting in fall 1997. The visits also included four pairs of visits performed at two different times of the day and three other groups of visits performed at three different times on the same day. Thirty-one visits to section 493011 included seasonal visits over 4 annual cycles starting in fall 1993, starting in fall 1994, and starting in fall 1996. The visits also included five pairs of visits performed at two different times of the day. Appendix B provides a detailed listing of design features and a profile-measurement history for each test section.

## CHAPTER 3. METHODS FOR ESTIMATING STRUCTURAL FACTORS

The PSG value is empirically estimated using profile data and the Westergaard curve-fitting procedure. This procedure assumes an idealized profile based on assumptions of linear temperature and moisture gradient throughout the full depth of the slab, which has ends that are unrestrained and a width that is infinite along the undeformed axis. The PSG is then estimated as the value required for the idealized profile to fit the measure profile along each slab. ${ }^{(2)}$

To calculate PSG, certain structural factors for each section needed to be estimated as inputs for the Westergaard procedure: elastic modulus of the PCC slab $(E)$, Poisson's ratio ( $\mu$ ), modulus of subgrade reaction $(k)$, and PCC slab thickness $(h)$. This analysis used both AREA and Best Fit methods for estimating structural factors, $k$ and $E$, which were evaluated in Long-Term Pavement Performance Program Determination of In-Place Elastic Layer Modulus: Backcalculation Methodology and Procedures (FHWA-HRT-15-036). ${ }^{(5)}$ The analysis resulted in two sets of structural factors used to compute PSG values.

## ESTIMATING LAYER THICKNESS AND POISSON'S RATIO

AREA and Best Fit methods used the same PCC layer thickness and assumed a $\mu$ of 0.15 . Generally, $\mu$ for PCC ranges from 0.15 to $0.20 ; 0.15$ typically represents concrete with a higher stiffness. Assuming the value of $\mu$ is reasonable, as minor changes in $\mu$ would not result in significant error in calculating the shape of the Westergaard idealized profile. The other structural factors ( $E, k$, and $h$ ) were more significant in determining the PSG.

The value for $h$ was taken from data table TST_L05B of the LTPP InfoPave ${ }^{\text {TM }}$ database. ${ }^{(8)}$ This value is the representative thickness of the PCC layer and is usually estimated based on pavement cores taken before and after each test section. The pavement cores were measured in accordance with LTPP protocol AC01. ${ }^{(8)}$ The thickness of a pavement layer from the beginning of a test section to its end is not perfectly uniform; averages from core measurements typically provide the best representation for the section as a whole.

## ESTIMATING STRUCTURAL FACTORS

Most test sections in the LTPP program have been sampled and have undergone laboratory material testing using LTPP testing protocols. ${ }^{(8)}$ LTPP data, however, do not provide information on the stiffness of treated bases. Material testing on treated bases was limited to compressive strength testing and was only performed on four SPS-2 test sections in Michigan. The stiffness of treated bases was necessary to estimate the modulus of subgrade reaction of a composite pavement. Additionally, the modulus of subgrade reaction was measured by remolding soil samples, which may not represent the in-situ condition of the material. Therefore, estimations of material properties using FWD backcalculation were used to provide consistent data. However, there is a small source of error that inevitably occurs with FWD backcalculation because of the compensating layer effect. This effect is common in pavements with layers that are not clearly defined, undistressed, and homogenous, and results in the modulus of layers being overestimated or underestimated relative to the modulus of an adjacent layer. This research evaluated the results from two methods, AREA and Best Fit, for estimating $E$ and $k$.

## ESTIMATING STRUCTURAL FACTORS USING THE AREA METHOD

The AREA method uses a backcalculation algorithm to estimate the radius of relative stiffness $(l), k$, and $E$. Unlike the Best Fit method, the AREA method is not iterative and is based on the AREA parameter. ${ }^{(9)}$ In either method, both $E$ and $k$ values have an inverse relationship in determining the FWD deflection basin because of the compensating layer effect. The following equations (figure 1 through Figure 8) were used to estimate $k$ and $E$.

The deflection basin parameter for the seven-sensor configuration $\left(A R E A_{7}\right)$ is the stiffness of the pavement layer relative to the subgrade. The value is computed using deflection measured by seven sensors at various offsets from the center of the load plate. Early FWD testing was performed using seven sensors with typical offsets of $0,8,12,18,24,36$, and 60 inches. The sensor at 8 inches would sometimes be moved to -12 (before the plate) for LTE testing. However, in 1999, the LTPP FWD equipment changed to nine sensors with typical offsets of -12 (before the plate), $8,12,18,24,36,48$, and 60 inches. For consistency, the $A R E A_{7}$ did not consider sensor offsets that only appear after 1999. The value is normalized to the deflection measured at the center of the load plate ( $d_{0}$ ), as shown in figure 1 .

$$
A R E A_{7}=4+6\left(\frac{d_{8}}{d_{0}}\right)+5\left(\frac{d_{12}}{d_{0}}\right)+6\left(\frac{d_{18}}{d_{0}}\right)+9\left(\frac{d_{24}}{d_{0}}\right)+18\left(\frac{d_{36}}{d_{0}}\right)+12\left(\frac{d_{60}}{d_{0}}\right)
$$

Figure 1. Equation. Calculation of the $\mathrm{AREA}_{7}$ parameter.
Where:
$d_{x}=$ peak deflection in inches at sensor offset.
$A R E A_{7}=$ a maximum value of 60 , which would be an extremely stiff pavement. A minimum value of 4 would be an extremely soft pavement. However, the minimum and maximum values would be too extreme to be achievable for actual pavement.

The equation in figure 2 is an empirical computation for the estimated radius of relative stiffness $\left(l_{e s t}\right)$ and is based on correlation to the $A R E A_{7}$ value. Both $l_{e s t}$ and $A R E A_{7}$ are values that express the relative stiffness between the pavement and the subgrade. Westergaard's idealized profile computes $l_{\text {est }}$ from $E, k, \mu$, and $h$. In theory, the $l_{\text {est }}$ value estimated from the $A R E A_{7}$ value could be input directly in Westergaard's curve-fitting procedure, which would minimize the error in the idealized profile created from the compensating layer effect between $E$ and $k$. For this reason, there is an expectation that PSG values derived from the AREA method would be more accurate than those derived using the Best Fit method because $l_{\text {est }}$ is derived from the shape of the deflection basin. The AREA method, however, relies on empirical data that precede LTPP. Therefore, the values produced by both methods were compared.

$$
l_{e s t}=\left\lceil\left.\frac{\ln \left(\frac{60-A R E A_{7}}{289.708}\right)}{-0.698}\right|^{2.566}\right.
$$

Figure 2. Equation. Calculation of $l_{\text {est }}$.
Figure 3 shows the equation for the nondimensional deflection coefficient at the center of the load plate ( $d_{0}^{*}$ ). The equation is used to estimate the modulus of subgrade reaction and the
nondimensional deflection under the center of loading plates based on the radius of relative stiffness.

$$
d_{0}^{*}=0.1245 e^{\left[-0.14707 e^{\left(-0.07555 l_{e s t}\right)}\right]}
$$

Figure 3. Equation. Calculation of $d_{0}^{*}$.
Figure 4 shows the equation for the estimated modulus of subgrade reaction ( $k_{\text {est }}$ ). $P$ is load magnitude. The equation is used to estimate the dynamic subgrade modulus estimated from the deflection measured at $d_{0}$.

$$
k_{e s t}=\frac{P d_{0}^{*}}{d_{0} l_{\text {est }}{ }^{2}}
$$

Figure 4. Equation. Calculation of $\boldsymbol{k}_{\text {est }}$.
The adjustment factor equation for $d_{0}\left(A F_{d_{0}}\right)$ is presented in figure 5. $L$ equals square slab size. This equation is based on $d_{0}$ and used to correct the estimated modulus of subgrade reaction for slab size, which was assumed to be an infinite plate in the Westergaard solution.

$$
A F_{d_{0}}=1-1.15085 e^{-0.71878\left(\frac{L}{l_{\text {est }}}\right)^{0.80151}}
$$

Figure 5. Equation. Calculation of $\boldsymbol{A} \boldsymbol{F}_{\boldsymbol{d}_{0}}$.
Figure 6 shows the adjustment factor equation for $l_{\text {est }}\left(A F_{l_{\text {est }}}\right)$. The equation is based on $l_{\text {est }}$ and used to correct the estimated $k$ for slab size, which was assumed to be an infinite plate in the Westergaard solution.

$$
A F_{l_{\text {est }}}=1-0.89434 e^{-0.61662\left(\frac{L}{l_{\text {est }}}\right)^{1.04831}}
$$

## Figure 6. Equation. Calculation of $\boldsymbol{A} \boldsymbol{F}_{\text {esst }}$

Figure 7 shows the equation for $k$. The equation is used to correct slab size and addresses the generalized limitations of Westergaard's infinite slab solution by correcting to a solution for a finite circular slab.

$$

$$
E=\frac{12\left(1-\mu^{2}\right) l_{e s t}{ }^{4} k}{h^{3}}
$$

## Figure 8. Equation. Calculation of $\boldsymbol{E}$.

## ESTIMATING STRUCTURAL FACTORS USING THE BEST FIT METHOD

The $k$ and $E$ using the Best Fit method is a computed parameter from the data table BAKCAL_BEST_FIT_SECTION_LAYER in the LTPP database. ${ }^{(8)}$ The computed unbonded modulus of the PCC layer was averaged to represent $E$ in this dataset.

The Best Fit method iterates through predicted deflection basins computed from $k$ and $l$. The Best Fit method solves for $k$ and $l$ values that show the best agreement between the profile of the measured and predicted deflection basins. ${ }^{(10)}$

In contrast to the AREA method, the Best Fit method does not rely on empirical data. The structural factors are estimated in the Best Fit method so that errors in the predicted deflection are minimized.

## COMPARING AREA AND BEST FIT METHODS

Figure 9 plots the $k$ values estimated from the AREA and Best Fit methods. The two methods produced similar $k$ values. The $k$ values from the AREA method were slightly higher than the values from the Best Fit method.

Source: FHWA.
Figure 9. Graph. AREA versus Best Fit method for estimating $\boldsymbol{k}$.
Figure 10 plots the $E$ estimated from the AREA and Best Fit methods. In several cases, $E$ was estimated by the AREA and Best Fit methods to be similar in value. However, in several other cases, $E$ was estimated to be slightly higher when using the Best Fit method than when using the

AREA method. This relationship is the opposite of $k$, but that was expected because $E$ and $k$ have a compensating effect on the deflection basin. The outliers in figure 10 indicated the AREA method overestimated $E$ compared to the Best Fit method. The difference in estimated values appeared more often in pavements with a lean concrete base (LCB). The $E, k$, and $l_{\text {est }}$ values for each section can be found in appendix F. Both Best Fit and AREA methods have estimated $E$ values higher than the expected average of $4,000 \mathrm{ksi}$ and in some cases higher than the expected maximum of $10,000 \mathrm{ksi}$.

Source: FHWA.
Figure 10. Graph. AREA versus Best Fit method for estimating $E$.
Figure 11 plots the $l$ values from the AREA and Best Fit methods. The plot illustrates the level of consistency between the two methods, especially considering the compensating effect between $E$ and $k$. The PSG value derived by fitting to a measured slab profile varies approximately with the inverse of the square of radius of relative stiffness for a given level of uplift at the slab ends (see Figure 14 for the equation to compute uplift at the slab ends). However, in terms of uplift, the curve-fitting results vary slightly for the differences between the AREA and Best Fit methods as shown in figure 11.

Source: FHWA.
Figure 11. Graph. AREA versus Best Fit method for estimating $l$.

## CHAPTER 4. PROFILE DATA ANALYSIS

## SYNCHRONIZATION

Profiles were extracted directly from the raw measurements and aligned using automated synchronization to an initial basis profile. In automated synchronization, each candidate profile is aligned to a basis measurement using cross-correlation. The procedure iteratively searched for the longitudinal offset and longitudinal distance-measurement scale factor that maximized the correlation between the candidate profile and the basis measurement. Computer programs used for automated synchronization performed cross-correlation after applying the IRI algorithm to the candidate and basis profiles.

Researchers used an automated synchronization procedure in these studies similar to a procedure applied in other studies of long-term roughness progression on LTPP SPS sites. ${ }^{(2,11-13)}$ In those studies, the procedure aligned the profiles by adjusting their longitudinal offset. In this study, the procedure aligned the profiles over their entire extent by adjusting the longitudinal offset and applying a scale factor to the recording interval of each candidate measurement. This procedure ensured consistency of joint locations over the complete monitoring of each section, which expedited joint finding and curl-and-warp analysis.

Table 4 lists the source (i.e., section or site) of the initial basis profiles by visit number, measurement date, and repeat number for each GPS-3 section and SPS-2 site. Appendix B provides additional information on visit numbers. A basis profile for each section was selected from raw profile data recorded at an interval of 1 inch or less. Profile data were collected at an interval of 1 inch or less starting in late $1996 .{ }^{(14)}$ For each SPS-2 site, basis profiles were selected from a profile measurement for which a complete set of event markers for section starting points were stored within the raw data. Spacing of event markers reconciled closely with the test section layout published in the construction reports. ${ }^{(15-19)}$

Table 4. Source of initial basis profiles.

| Section/Site | Visit | Measurement Date | Repeat |
| :---: | :---: | :---: | :---: |
| Section 063021 | 13 | $04-$ Dec-2004 | 1 |
| Section 133019 | 15 | 16-Oct-1997 | 1 |
| Section 183002 | 14 | $05-$ Dec-1997 | 1 |
| Section 273003 | 06 | 01 -Aug-1997 | 1 |
| Section 493011 | 12 | $05-$ Dec-1996 | 1 |
| Site 040200 | 08 | $08-$ Nov-2001 | 1 |
| Site 200200 | 06 | $03-$ Mar-1997 | 2 |
| Site 370200 | 12 | 14-Jul-2001 | 7 |
| Site 390200 | 03 | 08 -Dec-1997 | 2 |
| Site 530200 | 03 | 15-May-1998 | 1 |

For visits listed in Table 4, profiles of the remaining repeat measurements were automatically synchronized to the initial basis profiles. For subsequent visits, profiles were extracted from raw measurements of each test section using the following steps:

1. Synchronize profiles from the current visit to the basis measurement from the previous visit.
2. Designate the repeat measurement from the current visit with the highest correlation to the basis measurement from the previous visit as the basis measurement from the current visit.
3. Synchronize profiles from the current visit to the basis measurement from the current visit.
4. Repeat steps 1 through 3 until the final visit is complete.

Progress backward through the visits that precede the initial basis measurement using steps 1 through 4.

Before extracting the individual profiles as described in steps 1 through 4, the longitudinal offset and recording interval of raw measurements over SPS-2 test sites were automatically adjusted to improve their compatibility with the raw measurement designated for extracting initial basis measurements. The adjustment reduced the computation time needed during the iterative portion of the automatic synchronization process.

## QUALITY SCREENING

Visits to each test section included up to nine repeat profile measurements. Researchers selected the five measurements that exhibited the best agreement with each other for further analysis. Agreement between two profiles was judged by cross-correlating the profiles after applying the IRI filter. The average correlation level produced by these calculations provided a quantitative assessment of the repeatability within each set of repeat measurements. Overall, the selected data included 9,570 profiles from 1,941 section visits. Appendix C includes a list of the five selected repeat measurements from each visit to each section and a detailed description of the selection process.

## SUMMARY ROUGHNESS VALUES

Appendix D provides roughness progression plots for the 85 test sections included in this study. These plots show the left and right IRI values from each visit during the monitoring period. Appendix D also lists the Mean Roughness Index (MRI) and Half-car Roughness Index (HRI) of each section for each visit. These IRI, MRI, and HRI values are the average of the five repeat measurements selected in the quality screening. Appendix D also provides the standard deviation (SD) of the IRI for the five repeat measurements. High SD values help identify erratic roughness values resulting from transverse variations in the pavement surface caused by surface distresses.

## JOINT FINDING

Estimating curl and warp required isolating individual slab profiles by identifying joint locations. Researchers needed to identify joint locations consistently to help ensure changes in estimates of curl and warp were caused by genuine changes in slab movement rather than inconsistencies in the assumed slab boundaries. Precise identification (to the extent possible) of joint locations helped incorporate as much of the longitudinal range of profile within a slab as possible, particularly at slab ends where changes in elevation because of curl and warp are often the largest.

The algorithm for finding joint used in this research was similar to the algorithm applied in the Arizona SPS-2 site study of curl and warp. ${ }^{(2)}$ The method identified potential joint locations by seeking narrow downward spikes in each profile, prioritized locations where the spikes appeared consistently in repeated profile measurements and on both sides of the lane with provisions for skewed joints, and sought the set of prioritized locations that best approximated a known joint spacing or saw-cut spacing pattern. Appendix E describes the application of the method in detail.

The algorithm succeeded in locating all joints for profiles collected from December 1996 through January 2013 because those profiles were measured using narrow footprint-height sensors. A narrow footprint height sensor detects the height of the road surface by projecting (and detecting) light over a relatively small area on the pavement surface. As a result, narrow spikes appeared within the profiles at the locations of joint openings. Profile data collected before December 1996 were measured using height sensors with wider footprints and recorded after the application of low-pass filtering. Narrow spikes did not appear in the joints within in these profiles, and joint locations were assumed to be the same as the nearest visit for which the spike-detection algorithm succeeded. The profile synchronization process, described in the beginning of chapter 4, enforced consistency in longitudinal distance measurement for all profiles throughout the monitoring history of each section.

After January 2013, high-speed profilers recorded the profile measurements after applying low-pass filtering, which removed more short-wavelength content than the high-speed profilers used before January 2013. Downward spikes that appear in measured profiles at the joints did not stand out relative to other content within from the Washington SPS-2 site because those test sections included coarse surface texture. Joint locations for profiles collected after January 2013 at the Washington site were assumed to be the same as the last visit from before January 2013.

In some cases, the curl-and-warp analysis was terminated prior to the end of the monitoring period because of changes in the structural status of the test section. These changes included the installation of wide patches at joints on sections 200205 and 493011, diamond grinding of section 200210, patching and slab replacement on sections 390208 and 390212, and placement of an asphalt overlay on section 183002.

## CURL-AND-WARP ANALYSIS

Curl-and-warp levels present within each profile were estimated using slab-by-slab analysis of local profile segments. The procedure quantified the level of curl and warp on each slab using PSG. PSG is the gross strain gradient required to deform a slab into the shape that appears within the measured slab profile from a flat baseline. The PSG value for each slab was derived using a curve fit between the measured profile and an assumed slab shape predicted by the Westergaard equation. ${ }^{(20)}$ Appendix F presents the Westergaard equation and details about the curve-fitting procedure.

The Westergaard equation predicts the change in slab profile that has deformed in response to a linear strain gradient throughout its depth. The underlying model assumes that the slab rests on a dense liquid foundation. The equation includes slab length, Poisson's ratio, and radius of relative stiffness. In turn, radius of relative stiffness depends on elastic modulus, slab thickness, modulus of subgrade reaction, and Poisson's ratio.

For this study, material properties were assumed to be constant for a given section throughout the section's distance and monitoring history. LTPP database table L05B provided slab thickness values, which were primarily based on cores collected at the ends of each section. Elastic modulus and modulus of subgrade reaction were derived from FWD testing using two methods of analysis: AREA and Best Fit. Appendix F provides the material properties derived from each method.

The analysis for the structural properties produced a PSG value for each slab with every profiler's pass over an individual test section. Depending on the test section, this included 24 to 42 slabs that were within the test section boundaries. The analysis also included slabs at each end of the test section that were partially within the test section boundaries. A typical test section with 15 -ft-long slabs included either 32 or 33 slabs that were completely within the test section boundaries. The analysis was applied to 876,211 slab profiles.

PSG values for a given profile-measurement visit were analyzed by examining the distribution of PSG values within a test section and the spatial variation within a test section. The PSG values for a given slab were summarized by averaging PSG values for the five (or fewer, in some cases) repeat profile measurements from each visit to a test section. Sectionwide PSG averages were examined for long-term changes, diurnal variations, and seasonal variations over multiple visits.

## CHAPTER 5. CURL-AND-WARP BEHAVIOR

## DETAILED VIEW

Figure 12 shows a detailed view of the curl-and-warp behavior evident in the left profiles of section 133019 throughout that section's monitoring history. The figure shows whisker plots of PSG values from each set of five repeated profiler passes. PSG values were derived using an estimate of $l$ of 34.1 inches, which was produced by the Best Fit method. Positive PSG values correspond to downward curl.

Source: FHWA
Figure 12. Graph. Detailed view of curl-and-warp behavior in left profiles of section 133019.

Each row in figure 12 shows the minimum, 25th percentile, median, 75 th percentile, and maximum PSG value for 120 slab profiles. The 120 slab profiles correspond to 24 slabs within
the test section and 5 passes over the section per visit. The figure lists the date of each visit and the time of the first profiler pass. PSG values from individual slabs do not necessarily characterize curl-and-warp behavior because the profile of each slab includes other sources of irregularity, such as construction defects, grade changes, and distress. However, the median PSG values shown for each visit are associated with the amount of curl and warp present at the time because the influence of other irregularities is compensated over many slabs. Differences in median PSG values between visits are of interest because the differences are associated with cyclic and long-term changes in curl and warp.

Figure 12 illustrates several aspects about the curl-and-warp behavior of section 133019. First, the prevailing curl and warp on section 133019 is downward. The median value of the PSG is near zero for the first monitoring visit and is positive for all subsequent visits, which corresponds to downward curl. Second, the downward curl increases unsteadily over the first 20 years of monitoring. The overall increase in median PSG may have implications to the structural status of the section but is obscured by short-term changes. Third, section 133019 exhibits diurnal changes in slab curl. For example, figure 12 includes nine visits that occurred prior to 9:30 a.m. followed by a subsequent visit in the afternoon the same day. In every case, the median PSG value was higher in the afternoon, which is associated with an increase in downward curl caused by an increase in surface temperature. The two diurnal pairs shown in figure 12 with an initial visit after 10 a.m. did not follow this trend. Fourth, section 133019 may exhibit seasonal changes in curl.

Figure 12 includes seasonal measurements in 1996, 1998, and 2001. Median PSG values fluctuated throughout each interval, and fluctuations were the largest in 1996. However, explicitly distinguishing diurnal, seasonal, and long-term changes in PSG required knowledge of the temperature and moisture environment of the slab.

Finally, the magnitude of curl detected in the last two visits is reduced. Surface grinding performed in late 2010 reduced the roughness on this section. The postgrind PSG values are shown in figure 12 to illustrate the change in apparent slab curl. The difference in pregrind and postgrind PSG values does not, however, imply a change in the internal stress state of the pavement.

## TRENDS WITH TIME FOR SECTIONWIDE CURL

Figure 13 summarizes the trends in prevailing curl and warp with time on section 133019. The figure shows a weighted average of PSG values from each profile-measurement visit. Like the data in figure 12, PSG values were derived using an $l$ value produced by the Best Fit method. The weighted average incorporates slab-by-slab PSG values from repeat passes (typically five passes) selected for each monitoring visit. The contribution of the PSG value from each slab profile is weighted by slab length, which has a constant nominal value on section 133019. Figure 13 expresses the age of section 133019 in years since the date of construction for each visit.

Source: FHWA.
Figure 13. Graph. Average PSG values versus time using Best Fit method for section 133019.

Figure 13 illustrates the direction of slab curl and warp observed in section 133019 and the long-term trend. The figure also demonstrates the magnitude of seasonal and diurnal changes in curl relative to the prevailing level. Appendices G and H provide plots in the same format as Figure 13 for PSG values derived using the Best Fit and AREA methods, respectively, for each test section.

The trends in PSG derived using the Best Fit and AREA methods were similar. In the Westergaard deflection equation used to produce curve fits for estimating PSG, the uplift at the slab ends $\left(z_{0}\right)$ is proportional to the product of PSG and $l^{2}$, as shown in Figure 14.

$$
z_{0}=-P S G(1+\mu) l^{2}
$$

Figure 14. Equation. Uplift at slab ends.
Poisson's ratio $(\mu)$ was assumed to be 0.15 .
Fitted PSG values from the Best Fit and AREA methods correlate closely when they are scaled by the square of their respective estimates of $l$. Values of slab-end uplift for fitted profiles were closely correlated between the two methods. For example, plots in appendices G and H each include 1,877 PSG values for the left-side profiles. The corresponding uplift values range from -0.21 to 0.19 inches, and the largest difference between the AREA and Best Fit methods is 0.0026 inches. Therefore, results are provided for the Best Fit method only in the remainder of this discussion.

Figure 15 through Figure 20 summarize the curl-and-warp behavior of the test sections included in this study. The figures group SPS-2 test sections by site; the five GPS-3 sections appear in the same figure. These figures show the weighted PSG ranges observed over the monitoring period for each section included in this study. The figures show PSG values derived using the $l$ value produced by the Best Fit method.

## SPATIAL TRENDS

Some test sections exhibited spatial changes in PSG values. Figure 21 shows left PSG values for 34 slabs in section 040214 . Each value in the figure is the average over five repeated passes. PSG values transition from upward curl (negative values) at the start of the test section to values near zero at the end of the test section in profiles measured in winter 1994. These profiles were measured less than 4 months from the date the site was opened to traffic. Profiles measured in winter 2004 transition from downward curl (positive values) to upward curl (negative values) at the end of the test section. Karamihas and Senn illustrated the transition from downward curl to upward curl for the right PSG values from the same test section. ${ }^{(2)}$

Figure 21. Graph. Spatial variation in left PSG values for section 040214.
Figure 22 shows the spatial trend in left PSG values for profiles measured on section 040220. These profiles were measured 18.2 years after the site was opened to traffic. The transition toward a reduction in upward curl along section 040220 appeared in profiles from both sides. The reduction in upward curling was small early in the life of this section, increased over the first 18.2 years, and held steady over the rest of the monitoring period.

Source: FHWA.
Figure 22. Graph. Spatial variation in left PSG values for section 040220.
Figure 23 shows the spatial trend in left PSG values for profiles measured on section 200201. These profiles were measured 13.8 years after the site was opened to traffic. The negative PSG values over the last 60 ft of the section were observed on replacement slabs. The two slabs closest to the end of the section were replaced 3.4 years after the site was opened to traffic, and the two adjacent slabs upstream were replaced 10.1 years after the site was opened to traffic.

Source: FHWA.
Figure 23. Graph. Spatial variation in left PSG values for section 200201.
Additional examples of spatial trends in PSG are included in the following list:

- Section 133019 exhibited an increase in downward curl along its length throughout its monitoring history, except for when profile measurements were collected after surface grinding. The magnitude of the trend was strongest for right-side profiles.
- Section 183002 exhibited a decrease in upward curl along its length throughout the monitoring period. The magnitude of the trend was larger for left-side profiles than right-side profiles. The magnitude of the trend also increased for left-side profiles over the first 24 years of the monitoring period and was steady for several visits afterward.
- Section 200206 exhibited a decrease in downward curl along its length for part of the monitoring period for left-side profiles. The magnitude of the trend increased from 11 to 21 years after the date the site was opened to traffic and held steady afterward.

## CHAPTER 6. THEORETICAL IRI-PSG RELATIONSHIP

This section illustrates the relationship between IRI and PSG values using synthesized profiles. Synthesized profiles with curling are created using the Westergaard deflection equations. The relationship between IRI and PSG values is examined in the absence of other sources of roughness using the synthesized profiles. This section also examines the IRI-PSG relationship for profiles with curling and other sources of roughness by superimposing synthesized background roughness on the idealized deflection profiles.

## SYNTHESIZED PROFILES FOR CURL ONLY

Synthetic profiles of curl and warp are based are created using the Westergaard deflection equation in a repeating pattern. Figure 24 shows an example with a $15-\mathrm{ft}$ slab length $(b), l$ of 40 inches, $\mu$ of 0.15 , and PSG of $100 \mu \varepsilon / \mathrm{inch}$. The IRI of this profile is 207.6 inches $/ \mathrm{mi}$.

Source: FHWA.
Figure 24. Graph. Idealized profile with curling.
Figure 25 shows the variation in IRI with PSG for idealized profiles with a $b$ value of 15 ft and $l$ values of 25,40 , and 60 inches. As shown, IRI varies in proportion to the magnitude of PSG for a given combination of $l$ and $b$. This magnitude of the slope for a given combination of $b$ and $l$ is the same for negative values of PSG. This would not be the case, however, when the influence of faulting and downward spikes at joints are added.

Source: FHWA.
Figure 25. Graph. IRI versus PSG for various values of $\boldsymbol{l}$.
The slope defining the increase in IRI with PSG depends heavily on $l$. Figure 26 shows a reduced version of the Westergaard deflection equation.

$$
z(x)=z_{0} f(x, l, b)=-P S G(1+\mu) l^{2} f(x, l, b)
$$

Figure 26. Equation. Simplified Westergaard equation for slab deflection.
Idealized slab profiles have a shape that is a function of $b, l$, and distance along the slab $(x)$. The function $f$ has a unit upward deflection at the slab ends. The value of $z_{0}$ scales in proportion to PSG and in proportion to $l^{2}$.

Figure 27 demonstrates this relationship for $b$ values of 12, 15, and 20 ft . The figure shows the variation in IRI versus PSG slope with $l$. For each value of $b$, the IRI versus PSG slope varies in approximate proportion to $l^{2}$. Changes in the shape of slab profiles with $l$ cause minor deviations from a squared relationship not visible in figure 27. However, the squared relationship between $l$ and $z_{0}$ translates to an approximately squared relationship between the $l$ and the IRI versus PSG slope.

Source: FHWA.
Figure 27. Graph. IRI versus PSG slope versus $\boldsymbol{l}$.
For an evaluation of curl and warp that involves structural behavior, using PSG is a convenient way to quantify slab deformation because it offers a potential link to changes in the slab stress state at various times and absolute stress state in some cases. For the evaluation of functional behavior, such as evaluation of changes in IRI versus time, uplift provides a more convenient quantification of curl and warp. Uplift ( $z_{0}$ ), as defined implicitly in Figure 26, provides the upward deflection at the slab ends. For this discussion, the research team defines relative uplift $(\Delta z)$ for the Westergaard deflection equation as uplift relative to the slab center. As shown in Figure 24, the slab center also deflects. $\Delta z$ is defined as shown in figure 28, where $s \lambda, c \lambda, s h \lambda$, and $c h \lambda$ are trigonometric and hyperbolic functions of the argument $\lambda$.

$$
\Delta z=z(b / 2)-z(0)=-P S G(1+\mu) l^{2}\left(1-\frac{s_{\lambda} c h_{\lambda}-c_{\lambda} s h_{\lambda}}{s_{\lambda} c_{\lambda}-s h_{\lambda} c h_{\lambda}}\right)
$$

Figure 28. Equation. $\Delta z$.
Figure 29 shows the equation for $\lambda$.

$$
\lambda=\frac{b}{l \sqrt{8}}
$$

Figure 29. Equation. $\boldsymbol{\lambda}$.
Figure 30 shows the IRI for 0.01 inches of $\Delta z$ as a function of $l$ for $b$ values of 12,15 , and 20 ft . Figure 30 also shows that IRI increases as $b$ decreases for a given amount of $\Delta z$ because an approximately equal amount of slope variation is concentrated within a shorter distance when the slab is shorter. For each value of $b$, the IRI for a given amount of $\Delta z$ changes with $l$ because of changes in the shape of the slab deflection profiles. As $l$ reduces in relation to $b$, the deflection
profiles transition from an approximate parabolic shape to a profile that flattens in the middle. The result is a relative increase in the short-wavelength variation that contributes to the IRI.

Source: FHWA.
Figure 30. Graph. IRI per 0.01 inch of $\Delta z$.

## SYNTHESIZED PROFILES WITH BACKGROUND ROUGHNESS

When deflection caused by curl and warp and other sources of roughness are superimposed to establish a combined profile, some cancellation between the two sources of roughness occurs. In addition, variations of the apparent PSG values for individual slabs occur around the nominal value. This section demonstrates these phenomena by combining synthesized slab profiles with curling and profiles with nonperiodic background roughness. As in the previous discussion on synthesized profiles for curl, profiles are synthesized using the Westergaard deflection equation.

## Systematic Effects

Figure 31 shows the IRI versus PSG for profiles that combine synthesized profiles with slab curl and background roughness. The profiles were synthesized for 15 - ft long slabs and $l$ of 40 inches, which are shown in Figure 24. Background roughness was synthesized with IRI values of 50, 80, and 110 inches $/ \mathrm{mi}$. The line in Figure 31 that represents 0 inches $/ \mathrm{mi}$ shows the relationship between IRI and PSG for synthesized profiles with no background roughness added. This corresponds to the middle line in Figure 25.

Each point in Figure 31 shows the average IRI versus the average PSG for 15,000 simulated test sections. Each test section included thirty-three 15 -ft-long slabs totaling 495 ft . For each point, the simulation superimposed synthesized deflection profiles over 100 realizations of white noise slope, which were each 75,000 - ft long. This length includes 150 test sections with 33 slabs each and an additional 50 slabs for at the start. As described in the following sections, the IRI and PSG values for individual test sections vary around the averaged values shown in Figure 31 for individual sections.

Source: FHWA.
Figure 31. Graph. Average IRI versus PSG for curl and background roughness.
Previous research into the application of PSG proposed a linear relationship between IRI and PSG. ${ }^{(2,3)}$ Figure 31 shows that a linear fit approximates the relationship between IRI and PSG values when curl and warp account for a majority of the roughness. However, a linear fit does not approximate the relationship between IRI and PSG values when the magnitude of curl and warp is relatively low. Additionally, extrapolation of the IRI versus PSG slope from a range with substantial curl and warp to estimate the background roughness is not accurate.

If both profile components were random, Gaussian signals, a sum-of-squares model approximates the IRI of the combined profile $\left(I R I_{\text {Comb }}\right)$ as shown in figure 32.

$$
I R I_{\text {Comb }}=\sqrt{I R I_{\text {Curl }}^{2}+I R I_{B a c k}^{2}}
$$

## Figure 32. Equation. Simple expression for IRI Comb .

Where:
$I R I_{\text {Curl }}=$ the IRI of the synthetic profile of curl and warp, shown in the lower trace of Figure 31.
$I R I_{\text {Back }}=$ the superimposed background roughness.
When $I R I_{\text {Comb }}$ is estimated using PSG, the equation in figure 32 becomes the equation shown in figure 33.

$$
I R I_{\text {Comb }}=\sqrt{\left(P S G \frac{d I R I}{d P S G}\right)^{2}+I R I_{B a c k}^{2}}
$$

Figure 33. Equation. Estimated $\boldsymbol{I R I}_{\text {Comb }}$.

The derivative of IRI with respect to PSG ( $d I R I / d P S G$ ) is the theoretical IRI versus PSG slope established using synthetic profile of curl and warp, as shown in Figure 25. The equation in Figure 32 estimated $I R I_{\text {Comb }}$ to within 1.4 percent or less using the data from Figure 31. However, the equation in figure 33 overestimated $I R I_{\text {Comb }}$ with a systematic residual that increased with PSG because the synthetic profiles of curl and warp were not Gaussian. Less cancellation of roughness occurs when the profiles are combined than if both profile components were Gaussian. The equation in figure 34 estimates $I R I_{\text {Comb }}$ with absolute residual values of 0.60 inches $/ \mathrm{mi}$ or less and an SD of 0.21 inches $/ \mathrm{mi}$ when using data points from Figure 31.

$$
I R I_{\text {Comb }}=\sqrt{0.97347\left(P S G \frac{d I R I}{d P S G}\right)^{2}+I R I_{\text {Back }}^{2}}
$$

Figure 34. Equation. IRI $_{\text {Comb }}$ empirically estimated using PSG.
However, the factor applied to $I R I_{\text {Curl }}$ required to create the best fit may depend on $b$ and $l$.
The research in this report is concerned with predicting the roughness not caused by curl and warp (i.e., $I R I_{B a c k}$ ) using the overall IRI (i.e., $I R I_{\text {Comb }}$ ) and values of PSG derived from the profile in figure 35.

$$
I R I_{\text {Back }}=\sqrt{I R I_{\text {Comb }}^{2}-A\left(P S G \frac{d I R I}{d P S G}\right)^{2}}
$$

Figure 35. Equation. IRI $_{\text {Back }}$ empirically estimated using PSG.
Factor $A$ is introduced because the profile content caused by curl and warp is not random or Gaussian. The error in the sum-of-squares approximation is low for predictions of IRI $_{\text {Comb }}$ based on PSG and $I R I_{\text {Back }}$. Prediction of $I R I_{B a c k}$ from PSG and $I R I_{\text {Comb }}$, however, can yield a high systematic error when the background roughness is low relative to the roughness caused by curl and warp.

Figure 36 shows the prediction of background roughness by using the equation in figure 35 for combined profiles produced with actual $I R I_{B a c k}$ of 50 inches $/ \mathrm{mi}$. With no adjustment to account for non-Gaussian content (i.e., $A=1$ ), the error grows in approximate proportion to PSG squared. For higher values of $I R I_{B a c k}$, the error is lower. The absolute error in IRI reduced in inverse proportion to $I R I_{B a c k}$ and the percentage error in IRI reduced in inverse proportion to the square of $I R I_{\text {Back }}$. As shown in figure 36, the error is much lower with the adjustment applied (i.e., $A=0.97347$ ).

## Figure 36. Graph. IRI $_{\text {Back }}$ prediction.

## Random Effects

With background roughness added, PSG values for individual slabs vary from the nominal value. For the simulations used to produce the graph in Figure 31, the white noise slope profile with an IRI of 50 inches $/ \mathrm{mi}$ introduced slab-by-slab variation in PSG with an SD of $10.78 \mu \varepsilon / \mathrm{inch}$. This corresponds to a $b$ value of 15 ft and an $l$ value of 40 inches. The distribution closely approximated a Gaussian distribution and produced a value of 0.0035 in a Komoglorov-Smirnov test for the 495,000 simulated slabs.

The slab-by-slab variation in PSG values caused by background roughness averages out over many slabs. Figure 37 shows the result when 495,000 slabs are divided into 15,000 test sections containing 33 slabs each. The figure shows the distribution in sectionwide PSG for groups containing 33 slabs when $I R I_{\text {Back }}$ is 50 inches $/ \mathrm{mi}$ and the nominal PSG value is $-50 \mu \varepsilon / \mathrm{inch}$. For this distribution, the average is $-50.02 \mu \varepsilon /$ inch and the SD is $2.4 \mu \varepsilon /$ inch. Using an average of 33 slabs, which equals 495 ft , some of the scatter was eliminated.

Source: FHWA.

## Figure 37. Graph. PSG distribution with background roughness for $\mathbf{1 5 , 0 0 0}$ test sections.

For the simulations used to produce the graph in Figure 31, the variation in PSG grew in proportion to the $I R I_{\text {Back. }}$. However, the variation did not depend on the nominal PSG value. For PSG values ranging from -100 to $100 \mu \varepsilon /$ inch, the SD of sectionwide PSG values (averaged over 33 slabs) ranged from 2.36 to $2.42 \mu \varepsilon /$ inch with $I R I_{\text {Back }}$ of 50 inches $/ \mathrm{mi}$. At 80 inches $/ \mathrm{mi}$, the SD ranged from 3.78 to $3.87 \mu \varepsilon / \mathrm{inch}$, and at 100 inches $/ \mathrm{mi}$, the SD ranged from 5.20 to $5.33 \mu \varepsilon / \mathrm{inch}$. For longer sections, the variation in sectionwide averages decreased. For example, with $I R I_{B a c k}$ equal to 50 inches $/ \mathrm{mi}$, the SD in sectionwide PSG averaged over 66 slabs (i.e., a section length of 990 ft ) was $1.11 \mu \varepsilon / \mathrm{inch}$, and the SD in sectionwide PSG averaged over 165 slabs (i.e., a section length of $2,475 \mathrm{ft}$ ) was $0.66 \mu \varepsilon / \mathrm{inch}$.

## CHAPTER 7. OBSERVATIONS OF THE IRI-PSG RELATIONSHIP

A goal of this research was to examine whether the relationship between IRI and PSG could be generalized. For example, if field observations using FHWA and LTPP data analyzed in this work demonstrated agreement with the analytical results previously presented, the measurement effort needed to infer the contribution of curl and warp to the overall roughness of a test section would be reduced. Alternatively, if observations of the change in IRI with PSG values demonstrated a consistent relationship among the test sections analyzed in this study, some generalizations would be possible. This, however, was not the case. Although the sum-of-squared model fits the IRI versus PSG data well for cases that had sufficient data to capture short-term changes in curl and warp, the fitting coefficients were not consistent among test sections with the same slab length.

Figure 38 shows a curve fit produced by the sum-of-squares model for profiles in section 040213 of the FHWA dataset. The figure compares IRI to PSG for the right-side profiles measured during 16 seasonal and diurnal measurement visits to the section.

Source: FHWA.
Figure 38. Graph. Sample IRI versus PSG fit for the sum-of-squares model.
The fitted curve in Figure 38 was produced using the Levenberg-Marquardt algorithm for a nonlinear, least squares fit to the function shown in Figure 39.

$$
I R I=\sqrt{\left(P S G \frac{d I R I}{d P S G}\right)^{2}+I R I_{B a c k}^{2}}
$$

Figure 39. Equation. Fitting function for IRI versus PSG.

In the equation in Figure 39, IRI and PSG are measured. $I R I_{B a c k}$ and $d I R I / d P S G$ are fitted parameters. $I R I_{\text {Back }}$ represents a prediction of the IRI that would occur in the absence of slab curl and warp (i.e., background roughness). The coefficient $d I R I / d P S G$ represents an empirical estimate of the IRI versus PSG slope that would exist in the absence of background roughness.

Table 5 shows the results for 38 curve fits applied to the FHWA dataset. The table includes only test sections monitored seasonally and diurnally and only with a nominal slab length of 15 ft , which are sections within the core experiment from SPS-2 sites. Table 5 lists cases in which the curve fit produced a residual less than 2.4 inches $/ \mathrm{mi}$ and the 95 -percent confidence interval for the IRI versus PSG slope was less than 10 percent of the fitted value. Table 5 also lists the two fitted coefficients and their 95-percent confidence intervals and the high and low PSG values included in the observations. Most of the excluded data produced high 95-percent confidence intervals because the PSG values were low or changed very little.

Table 5 also includes the coefficients produced by fitting the IRI to relative uplift ( $\Delta z$ ) using the sum-of-squares model (Figure 40).

$$
I R I=\sqrt{\left(\Delta z \frac{d I R I}{d \Delta z}\right)^{2}+I R I_{B a c k}^{2}}
$$

Figure 40. Equation. Fitting function for IRI versus $\Delta z$.
In the equation in figure $40, d I R I / d \Delta z$ is a fitted value that represents the IRI versus relative uplift slope that would exist without other sources of roughness. Figure 40 provides the relationship between $\Delta z$, PSG, and $l$. Unlike the IRI versus PSG slope, the slope between IRI and $\Delta z$ does not vary in proportion to the square of $l$.

As shown in Figure 30, the fitted value of $d I R I / d \Delta z$ is expected to be consistent over a large range of $l$ values and have a value near 800 inches $/ \mathrm{mi} / \mathrm{inch}$. It is not consistent, which shows that the relationship between the IRI and curl and warp cannot be generalized solely on structural properties. The individual curve fits often produced low residuals for individual sections when observations over a sufficient range of PSG values were available (Table 5). The data characterize the relationship between IRI and curl and warp for the individual test sections that produced the data.

Table 5. IRI versus PSG fitted coefficients.

## CHAPTER 8. CORRELATION TO ENVIRONMENTAL FACTORS

The curl-and-warp response in PCC pavements has been attributed to temperature and moisture gradients. Pavement surface is directly exposed to temperature and moisture from sunlight and precipitation, either of which can then permeate the pavement. Moisture can also permeate upward from the ground and become trapped underneath the pavement. In either case, the top and bottom of the PCC pavement layers are exposed to different environmental conditions. This difference in conditions is measured using a temperature or moisture gradient that expresses a change in temperature or moisture relative to the depth of the pavement.

The relationship of moisture and temperature to pavement depth is not perfectly linear, and the gradients produced in each slab are not identical. The design of a test section assumes a certain amount of uniformity. However, there are variations in construction methods (e.g., finishing and curing), subpavement conditions, and drainage that affect individual slabs. Researchers have observed that some slabs in a test section may curl up while others curl down. Some slabs may crack and some may have voids underneath the pavement. Portions of this study assume that the average curling across a test section should reflect the behavior of most slabs. However, in sections with near equal amounts of slabs curled up and curled down, averaging PSG over the test section may introduce variability into the correlation analyses.

PCC has higher compressive strength than tensile strength. Accordingly, PCC's design is typically controlled by its flexural strength. Internal stresses from curling and warping can magnify external bending stresses and cause different types of slab failures. Changes in temperature can cause concrete to expand or contract, and evaporation of moisture in the concrete can cause shrinkage. When the top or bottom of concrete pavement expands, contracts, or shrinks at a faster rate than the other side, the shape of the pavement curls or warps from uneven internal stresses. An upward curl can cause corner breaks from high stress at the top of a slab. A downward curl may result in transverse cracking from high stress at the bottom of a slab.

An upward pavement curl from temperature gradients usually occurs at night when the temperature at the bottom of a slab is greater than the temperature at the surface. This happens because pavement stores heat during the day but at night the surface of the pavement cools faster than the bottom of the pavement, which creates a temperature differential. By the next morning, the bottom of the pavement would have cooled off in time to have the pavement surface heat again from daytime temperatures. During the day, the temperature at the top of the pavement is higher than at the bottom, which causes a downward curl. Concrete pavement can cycle between relatively upward- and downward-curl behavior through daily temperature fluctuations (diurnal cycling). Curling is not typically considered to cause permanent curvature but is unknown how it might interact with drying shrinkage on a seasonal cycle. Seasonal temperature variation adds yet another level to this trend as hot summer days will create higher temperature differentials than colder winter days.

Warping caused by the moisture gradient in concrete pavements is typically upward. The moisture gradient occurs due to a cycle of wetting and drying at the top of the slab while the bottom of the slab remains saturated. Downward warping may occur in rare occasions where the moisture content is higher at the top of the slab than at the bottom, such as wetting of the
pavement surface following a long dry period. As the concrete dries, it shrinks, and when one side (i.e., top or bottom) shrinks more than the other side, internal stresses cause curvature. The shrinkage that occurs through each cycle of wetting and drying is partly irreversible, which could cause the pavement to incur permanent and incremental changes in the slab curvature.

Slab curvature can occur over time and at the time of construction because there are two types of shrinkage-drying and autogenous-with different mechanisms that can cause the slab to warp. Drying shrinkage happens over time as the pavement undergoes wetting and drying from changes in relative humidity. Autogenous shrinkage can cause the pavement to warp while it cures during construction. Autogenous shrinkage occurs while the pavement has yet to set; therefore, the built-in curvature that is initially observed in a new pavement is expected to flatten because of concrete creep (the permanent deformation of concrete from persistent loading). Drying shrinkage is driven by the loss of capillary water through evaporation. Water in the capillaries becomes saturated from the humidity in air-entraining voids. When the water in the capillaries evaporates, the hydrate particles contract, causing tensile stress.

Shrinkage in concrete pavements transpires exclusively in the paste component of the mixture and not the chemically inert aggregate. The paste is made from water and cement that undergoes hydration, causing the concrete to harden. Differences in moisture and temperature during the initial curing process cause the concrete to form an initial curvature. High-strength concrete with higher volumes of paste can cause even higher amounts of autogenous shrinkage, thus resulting in more-significant curvature. The use of curing compounds and methods and construction practices can also affect the initial curl. The initial curing process can also impact how the pavement behaves over time by altering its shrinkage potential.

Minor variability in construction methods, subsurface nonuniformity, and localized environmental conditions can often enforce a butterfly effect, which compels slabs that were designed equally to behave differently over time. This analysis generalized the initial curl and change in curl over time of a test section and correlated these two measures of curl to environmental and structural-design factors.

## DETERMINING PSG PREDICTION VALUES

Time-series analysis of PSG values suggested that pavements tend to start out at an initial curl-and-warp state and steadily change in curl-and-warp amount as the pavement ages. After approximately 10 years, the change in the amount of warping either plateaued or became highly variable. The reasons for this variability include slabs reaching a maximum amount of permanent warp and cracking from distress. Figure 41 demonstrates this trend in eight randomly chosen sections. Of the 83 test sections evaluated, data typically showed a linear trend in PSG values in the first 10 years of the pavement's life. This is a general observation and varies depending on the performance and shrinkage potential of specific sections or slabs. In some cases, this trend is less obvious, as seen in sections 390263 and 493011. In the case of section 133019, a 10-year trend does not exist because this section entered the LTPP program several years after construction. Of the five GPS-3 sections selected for analysis, only 273003 and 493011 entered the LTPP program in time for FWD testing to occur within the first 10 years. Table 31 in appendix B includes the construction dates of the selected GPS-3 test sections.

Figure 41. Graphs. Examples of PSG values over time for specific sections.
PSG values were averaged from each slab within a test section. Individual slabs deteriorated at different rates and caused variability in the average PSG for each section. The slabs also curled at different rates or directions, likely because of variations in construction or environmental factors. Additionally, the profile measurements used to compute PSG were measured at different times of the day or during different seasons, which caused variations in temperature and moisture gradient. Given these sources of variability, researchers found it difficult to observe a continuous trend in PSG. However, this variability became more significant as the pavement aged.

For this analysis, linear regression of PSG was performed on data from the first 10 years after construction. The regression intercept was the initial PSG value after construction $\left(P S G_{i}\right)$ and the regression slope was the rate of change in PSG value after construction ( $P S G_{s}$ ). Figure 42 and Figure 43 show a histogram of PSG intercept and slope by site with average annual temperature and relative humidity. The PSG regression values for each test section can be found in appendix I.

Source: FHWA.
Figure 42. Graph. PSG intercept histogram by SPS-2 site.

Source: FHWA.
Figure 43. Graph. PSG slope histogram by SPS-2 site.
The data showed that most test sections, regardless of climatic condition, started out with no initial curvature. However, there were multiple test sections that had an initial curvature. Arizona had multiple sections that started with strong upward curvature. Ohio also had a few sections with moderate upward curvature. Kansas had three sections with slight downward initial curvature.

Sites with high relative humidity and low temperatures showed less long-term change in PSG than sites with low humidity and high temperatures. Several Arizona sites showed an increase in upward curl over time. As the average annual temperature decreased, the number of sites with a
negative value for $P S G_{s}$ (indicating an upward change in curvature) decreased. Ohio had the most sites with a positive value for $P S G_{s}$ (indicating a downward change in curvature). Nonzero $P S G_{s}$ values imply that periodic incremental permanent changes in curvature occurred over 10 years. Warping is the expected cause of permanent changes in curvature, which theoretically should be upward because of shrinkage from the evaporation of moisture. However, several test sections curled downward as the annual average temperature decreased. This suggests two possibilities: downward curling commonly associated with the temperature gradient can contribute to permanent curvature in colder regions, or the moisture gradient that causes permanent warping tends to be inverted in colder regions. It is also possible that this trend was coincidental because of the limited number of test sites in the study.

## DETERMINING ENVIRONMENTAL FACTORS

Temperature gradient ( $\Delta T$ ) was estimated as the average linear regression slope of temperature measurements taken at various pavement depths. These subsurface measurements were obtained from the LTPP database and taken during FWD testing. Table 6 shows how the temperature and humidity data were summarized from the Modern-Era Retrospective Analysis for Research and Applications (MERRA) climate database. ${ }^{(21)}$ Climate factors for each SPS-2 site can be found in table 54 and table 55 in appendix I. Several climate indices were also analyzed, including annual precipitation and freezing index. These factors, however, did not show significant correlation to PSG. The average annual precipitation and freezing index were of interest to researchers because LTPP defines climatic region using criteria for these indices.

Table 6. Climatic factors and their variables for PSG correlation.

| Climatic Factors | In the First Month <br> After Construction | In the First 10 Years <br> After Construction |
| :--- | :---: | :---: |
| Average temperature | $T_{0}$ | $T_{1}$ |
| Average relative humidity | $H_{0}$ | $H_{1}$ |
| Average difference between the maximum and <br> minimum daily temperature | $\Delta_{T 0}$ | $\Delta_{T 1}$ |
| Average difference between the maximum and <br> minimum daily relative humidity | $\Delta_{H 0}$ | $\Delta_{H 1}$ |

Table 7 shows the structural design factors considered in the analysis. Paste volume was of interest because the shrinkage in the paste causes warping. Paste volume was expressed as percentage of the total mix. The total quantity of paste depended on the dimensions of the slab (i.e., length, width, and thickness). Thickness of base layers, elastic modulus of the PCC, and flexural strength of PCC were also considered in the analyses.

Table 7. Climate analysis: structural design factors for PSG correlation.

| Design Factor | Variable |
| :--- | :---: |
| Average slab width (ft) | $W_{\text {slab }}$ |
| Average slab length (ft) | $L_{s l a b}$ |
| Average layer thickness of PCC (inch) | $h_{P C}$ |
| Average layer thickness of base (inch) | $h_{B}$ |

## CORRELATING PSG AND ENVIRONMENTAL FACTORS

Predicting initial PSG values using all identified coefficients showed poor correlation. The RStudio ${ }^{\circledR}$ software was used for linear regression analysis and results can be found in appendix I. ${ }^{(22)}$ RStudio identified the most significant coefficients but was unable to provide a solution with a good fit. The model for $P S G_{i}$ and $P S G_{s}$ had R-squared values that ranged from 0.60 and 0.47. The most significant coefficients for $P S G_{i}$ were humidity and PCC/permeable-asphalt-treated base (PATB) layer thicknesses. For $P S G_{s}$, the most significant coefficients were paste volume, PCC elastic modulus, and LCB layer thickness.

Treated-base (i.e., PATB and LCB) thickness had a significant impact in the all-inclusive model; therefore, researchers determined that base type was potentially a classifier for the prediction model. Therefore, three prediction models were developed for each base type: granular base (GB), LCB, and PATB. Separating the models by base type produced models with significantly better fits; it also established that base type plays an important role in determining curling-andwarping behavior. The analysis resulted in the following linear models.

Figure 44 and Figure 45 show models for predicting $P S G_{i}$ (i.e., initial curvature) and $P S G_{s}$ (i.e., change in curvature after construction) using climatic and structural factors.

Table 8 describes the linear regression coefficients in Figure 44 and Table 9 describes the linear regression coefficients in Figure 45.

$$

Figure 45. Equation. Calculation of the change in $P S G_{s}$ using climatic and structural factors.

Table 10 summarizes the statistical outputs for all prediction models identified in appendix I. Two key observations can be made from the regression statistics in Table 10:

- When predicting $P S G_{i}$, the model for GBs had the least error and the model for PATBs had the most error.
- When predicting $P S G_{s}$, the model for GBs had the most error and the model for treated bases (i.e., PATB and LCB) had the least error.

These observations imply that autogenous shrinkage had more predictable effects on pavements with GBs and that drying shrinkage had more predictable effects on pavements with treated bases. The observations also mean the material properties of bases can change over time, causing models for $P S G_{s}$ to be more unpredictable in the case of GBs, which are typically more erodible than treated bases.

Table 10. Climate analysis: summary of prediction model statistics.

| Model <br> Statistic | GB <br> Base Type | PATB <br> Base Type | LCB <br> Base Type |
| :--- | :---: | :---: | :---: |
| $P S G_{i}$ model - Residual standard error | 0.355 | 0.359 | 0.486 |
| $P S G_{i}$ model - Multiple R-squared | 0.805 | 0.673 | 0.780 |
| $P S G_{i}$ model - Adjusted R-squared | 0.502 | 0.368 | 0.437 |
| $P S G_{i}$ model - F-statistic | 2.654 | 2.205 | 2.273 |
| $P S G_{i}$ model - p-value | 0.072 | 0.070 | 0.109 |
| $P S G_{s}$ model - Residual standard error | 0.109 | 0.033 | 0.072 |
| $P S G_{s}$ model - Multiple R-squared | 0.576 | 0.810 | 0.751 |
| $P S G_{s}$ model - Adjusted R-squared | -0.083 | 0.632 | 0.363 |
| $P S G_{s}$ model - F-statistic | 0.875 | 4.563 | 1.938 |
| $P S G_{s}$ model - p-value | 0.603 | 0.003 | 0.160 |

Figure 46 shows the plots by base type comparing predicted $P S G_{i}$ and $P S G_{s}$ (from environmental/structural factors) to the measured $P S G_{s}$ (from profile analysis). The poorest prediction was the $P S G_{s}$ of pavements with GB. Several GB sections with large amounts of upward or downward curl tended to show poor correlation to climatic factors.

In contrast, the $P S G_{s}$ predictions for pavements with treated bases were significantly better, which indicates that climatic factors have a more consistent effect on the curl and warp of pavements with treated bases. Pavements with treated bases tended to have more downward than upward curvature over time. Upward curvature is typically driven by the moisture gradient;
therefore, downward curvature may be the result of another factor that contributed to warping in treated base pavements.

It was more difficult to determine how the predicted value compared to the measured value in the case of the $P S G_{i}$ because for most sections the amount of initial curvature was not significant. There were a few sections in which initial curvature was significantly upward. These sections had granular or LCBs and had better prediction models because the spread of initial $P S G_{i}$ values was wider.

## SIGNIFICANCE OF ENVIRONMENTAL FACTORS

Based on the $p$-values of the prediction model, Table 11 shows coefficients that have the most significance in predicting $P S G_{i}$ and $P S G_{s}$. The thicknesses of certain layers had significant influence on the prediction model. Paste volume and PCC modulus also had a significant effect for pavements with GB and PATB. However, for pavements with LCBs, temperature and humidity coefficients were more significant.

The coefficients that had the most significance in determining the PSG prediction models were identified using the $\operatorname{Pr}(>|t|)$ value ( $p$-value in RStudio for the $t$-test) shown in Table 11. The $p$-value determines the chance the result was obtained by random error. For example, a $p$-value of 0.1 indicates there was less than a 10-percent chance that the result is from random error. $p$-values greater than 0.1 are usually interpreted as having no evidence that the null hypothesis holds, which means that there was a good chance the result was from random error. However, this interpretation could also have been an oversimplification and high $p$-values could result from having a small sample size (i.e., low degrees of freedom). The following observations were made using the $p$-values from $P S G_{i}$ and $P S G_{s}$ prediction models:

- GB: The $P S G_{i}$ was mostly controlled by the thickness of the base and treated subbase layers, the dimensions (length and width) of the PCC slab, the paste volume, and flexural strength. The $P S G_{s}$ was mostly controlled by the stiffness of the PCC slab, the thickness of the granular subbase and treated subbase layers, and paste volume. The model for $P S G_{i}$ had lower R-squared values than the model for $P S G_{s}$ ( 0.805 versus 0.576 ), suggesting that the initial curl was easier to predict than the change in curl over time for pavements with a GB.
- PATB: The $P S G_{i}$ was mostly controlled by the paste volume and the thickness of the PCC slab and base layers. The $P S G_{s}$ was mostly controlled by the thickness of the PCC slab, base, and subbase layers. The model for $P S G_{i}$ has higher R-squared values than the model for $P S G_{s}$ ( 0.673 versus 0.810 ), suggesting that the change in curl over time was easier to predict than the initial curl for pavements with PATB.
- LCB: The $P S G_{i}$ was mostly controlled by the PCC slab stiffness, temperature gradient, and thickness of the granular base layers. The $P S G_{s}$ was mostly controlled by the average annual relative humidity and temperature, average daily difference between maximum and minimum temperature and humidity, and thickness of the slab length. The model for $P S G_{i}$ has higher R-squared values than the model for $P S G_{s}$ ( 0.780 versus 0.751 ), suggesting that the initial curl was easier to predict than the change in curl over time for pavements with LCB.

The best prediction model was for the change in PSG of pavements with LCBs. This model met the expectation that temperature and humidity controlled the long-term curling and warping behavior of a PCC pavement. Slab length also showed good correlation in predicting $P S G_{s}$ for pavements with LCBs. The $p$-values on these coefficients were all less than 0.01 , which indicated that there was strong evidence the null hypothesis did not hold. The other PSG prediction models depended mostly on the structural factors of the pavement (e.g., layer thickness, stiffness, paste volume). Compared to the impact of structural factors, climatic factors had a secondary impact on PSG prediction models.

In the case of structural factors, $p$-values were typically larger than 0.1 and indicated either that the model likely resulted from random errors or the sample size was not large enough. These structural properties likely contributed to an unknown structural parameter of mechanical behavior. The significance of the thickness of pavement layers may indicate that the dynamics of the pavement structure played some role in the curl behavior. The significance of pavement-layer thickness was especially true for pavements with more flexible base types, such as GB and

PATB. The change in PSG of pavements with LCB was strongly controlled by climatic effects of humidity, temperature, and slab length.

## SUMMARY OF FINDINGS

Researchers developed six models to predict the initial curl and warp of test sections of different base types and the rate of change in curl and warp in the first 10 years after construction. The simple linear regression analysis produced interesting results that described curl-and-warp behavior in LTPP concrete pavements. The models were developed using RStudio software, and results of the linear regression analysis can be found in the climate analysis section of appendix I. ${ }^{(22)}$

The initial curvature of many of the test sections was not overly significant, which could be because of the effect of concrete creep while the pavement was curing. Some pavements started out with an upward curvature; these pavement sections had either granular or LCBs. Pavements with PATBs typically had very little initial curvature. Humidity affected initial curvature for all bases types (the third most significant coefficient), but initial curvature was primarily controlled by nonclimatic structural factors (i.e., layer thickness, paste volume, stiffness). However, the $p$-values of coefficients in the prediction models were typically high, suggesting that correlations could result from random error. For example, paste volume only appeared to have significance in the model for PATB pavements (when predicting $P S G_{i}$ ), but the effect of paste volume may have been coincidental since $p$-values were slightly high. In general, these models indicated that base
type, pavement structure, and humidity strongly impact the built-in curvature in PCC slabs, and pavements typically start out with little curvature.

The change in PSG over time was the best way to identify curling behavior. Models that predicted this change were consistent for pavements with treated bases (i.e., PATB and LCB). PCC elastic moduli were significant in the $P S G_{s}$ models for GB, PATB, and LCB pavements. Paste volume was significant only in GB and LCB pavements. The thickness of the PCC layer was significant in test sections with treated bases. Temperature and humidity were significant for GB test sections only, and the temperature gradient had a minor effect for LCB test sections. In general, these results indicated the stiffness of the PCC was the most common coefficient with significance. The effect of base types caused certain factors to have more influence on the prediction model than other factors. The $P S G_{s}$ models for treated bases had the least amount of error and the primary coefficient in those models was PCC thickness. In the case of test sections with GBs, PCC thickness was not as significant as climatic factors; therefore, the model was less reliable.

Other climatic factors considered included the total annual precipitation and the freezing index, but these factors had no effect in the linear regression analysis. The precipitation amount and days below freezing were not as important to curl-and-warp behavior as the annual average temperature and humidity. To predict initial curling in a pavement, researchers determined that climate data (temperature and humidity) averaged over the first month after construction had a better correlation than climate data averaged over the first 10 years. Likewise, prediction models for the change in curl over time were better when using climate data averages from the first 10 years after construction rather than the first month.

## CHAPTER 9. CORRELATION OF PSG TO FWD RESULTS

Pavements with uplift from curl and warp can behave differently than level pavements that are fully supported by their base when a load is applied. The uplift often causes a void or soft soil underneath the pavement at the raised part of the slab. When a load is applied to the uplifted part of the slab, the slab can deflect freely until it contacts the underlying layer. Once the pavement is supported by the underlying layer, the pavement structure can act in unison to resist the applied load. While under load, the total deflection of the slab is partly due to the uplifted deflection of the curled slab and partly to the deflection from loading the pavement.

The unloaded deflection should remain constant regardless of the amount of load being applied, but the deflection from loading should be proportional to the applied load. Analyzing FWD testing data at different load levels produced the amount of linear elastic deflection in proportion to the applied load and distinguished the amount of unloaded deflection from the loaded deflection. This unloaded deflection was correlated to PSG, an indicator of the tensile strain in the slab resulting from curl and warp.

## DEVELOPING DIs

Per LTPP tests and protocols, FWD testing on rigid pavements was performed at three load levels. ${ }^{(23)}$ Typically, as the load level increases, the amount of deflection in the pavement proportionally increases. Performing linear regression analyses on the loads and deflections yielded a slope and an intercept. The DI is the unloaded deflection of the pavement. In theory, pavements with an upward curl should have an unloaded deflection near the edge of the slab, and pavements with a downward curl should have an unloaded deflection near the center of the slab. However, this assumption also assumes the pavement and underlying layers are not significantly deteriorated. Cracked slabs, air voids, or soft soils could also impact the DI value.

Figure 47 demonstrates how error can be introduced into the DI value depending on the actual relationship curve between load and deflection. The calculated DI may result partly from the uplift from curl and warp and partly from the reaction of the base or subgrade. Soil liquefaction may cause soil to lose stiffness in proportion to the applied load, resulting in higher deflections. Liquefaction is especially common in freeze-thaw areas, where thawed subgrade may be sandwiched between the pavement and frozen subgrade. The viscoelastic nature of asphalt-bound layers may cause asphalt-treated bases in concrete test sections to increase in stiffness with repeated loading. The load shown in Figure 47 is the net of the applied dynamic load from the FWD and the uplift force from the curvature of the slab. This uplift force is unique to each slab and test point. Uplift at the slab corner may react differently than uplift at the center. When at the corner, doweling and aggregate interlock between the adjacent slab and the shoulder may influence the DI value. Because of these potential sources of error, the DI value may be subject to interpretation based on the structural properties of the slab and not purely the curvature from curl and warp.

## B. Diagram of negative-loaded DIs.

Figure 47. Illustrations. Demonstration of error in the linear elastic calculation of DIs when there is a nonlinear relationship between deflection and load.

LTPP FWD testing is performed at specific locations with respect to the slab. This testing allows for a DI value to be calculated for each location on the slab. Figure 48 shows a diagram of FWD test location relative to the slab. Table 12 describes the location of FWD test point IDs relative to the JPCP slab. However, because FWD testing is performed in order of test point type and not slab-by-slab, a time gap exists between tests performed at each location on the slab. The time gap can be an issue if temperature or other environmental conditions change during the day and cause a change in the curl state of the slab. For example, the curl state of the slab may be slightly different when FWD testing was conducted at the midslab location than when testing was conducted at the corner. Depending on the lane width of the test section, FWD testing on a $500-\mathrm{ft}$ SPS-2 section will typically take 1 to 5 hours. Table 12 describes the location of each FWD test point ID illustrated in Figure 48.

Table 12. FWD test point IDs and locations.

| Test Point ID | Location |
| :---: | :---: |
| J1 | Midlane, midslab |
| J2 | Pavement edge, approach joint edge |
| J3 | Pavement edge, midslab |
| J5 | Outer wheel path, approach joint edge |

## CURL AND WARP IN DIs

In most cases, time-series plots of DI values did not provide sufficient information to identify the curl state of the pavement. Intervals between FWD tests ranged from 4 months to 12 years ( 3.2 years on average). Testing occurred in different seasons or at different times during the day. Testing interval variations resulted in different temperature and humidity conditions for each test. FWD testing was typically not performed in concurrence with profile testing; therefore, each form of pavement testing was typically performed in different environmental conditionsconditions that are known to cause diurnal and seasonal fluctuations in a pavement's curl-andwarp state. Additionally, the curling of each slab in a section may affect the DI values to a different extent. Compounding all these factors of variability added significant background noise to trend analysis using only the DI value.

## CORRELATING PSG AND DIs

A positive DI value at J1 (slab center) indicates the amount of downward curl, and a positive DI value at J2 (slab corner) indicates the amount of upward curl. Therefore, the difference between $D I_{J 1}$ and $D I_{J_{2}}$ will indicate the overall curl direction, as shown in Figure 49. A positive $\Delta D I$ indicates a downward curl and a negative $\Delta D I$ indicates an upward curl.

$$
\Delta D I=D I_{J 1}-D I_{J 2}
$$

## Figure 49. Equation. Calculation of $\Delta D I$.

Where:
$D I_{11}=$ DI at FWD test point J1 (slab center).
$D I_{52}=$ DI at FWD test point J2 (slab corner).

The DI values at J3 and J5 were also evaluated but no significant trends were found. Test point J 2 is farther from the pavement's center than J3 and provided more pronounced and consistent DI values. The DI values at J 5 also did not provide any meaningful trends in relation to the curl state. The uplift from curling is more prominent across the length of the slab than the width; therefore, a common mitigation for pavement curling has been to design a pavement using shorter slab lengths.

Certain SPS-2 test sections have 14-ft-wide slabs that included additional test points: J7 and J8. These slabs were typically wider than the travel lane and extend into the shoulder. At widened test sections, J2 is the corner at the travel lane edge and J7 is farther out at the corner of the pavement edge. Likewise, J8 is farther out than J3. However, because only half of the SPS-2 test sections had 14 -ft-wide slabs, the DI values at J 7 and J 8 were not evaluated for a comprehensive trend analysis. Slab width may affect curvature; therefore, evaluating test points at different locations relative to the slab midpoint could potentially skew the results. Based on a quick investigation, deflections at J 7 and J 8 were similar enough to deflections at J 2 and J 3 that that these values did not have a significant difference in how they should be interpreted.

Figure 50 shows the distribution of DI values evaluated at FWD test locations. DI values at J1 (slab center) were typically lower than at other locations. Because of this, $D I_{J_{2}}$ usually controls the computed value of $\Delta D I$. The DI at J 2 typically had higher absolute values than other locations (except J7). J2 and J7 followed the same distribution of DI values. The only major difference between J 2 and J 7 was that twice as many tests were performed on J ; the same difference also applied to J3 and J8. DI values followed the same distribution and twice as many tests were performed on J3 than J8. The distributions in J2 and J3 followed a similar pattern, but the absolute DI values at J2 were typically larger than at J3.

Source: FHWA.
Figure 50. Graph. Distribution of DI values by FWD test-point location.
Figure 50 also describes the characteristic differences between slabs that are curled up and curled down. Assuming DI values near zero represent slab without curvature, the distribution of DI values for slabs that curled up was different from the distribution of slab were curled down.

These distributions suggested the true DI value for a slab with no curvature is slightly negative and not zero. Slabs that curled up (positive $D I_{J_{2}}$ and negative $D I_{J_{1}}$ ) have larger absolute DI values than slabs that curled down (negative $D I_{J_{2}}$ and positive $D I_{J_{1}}$ ). This finding suggested that the degree of curvature for slabs that curled up was typically greater than the amount of curvature in slabs that curled down.

Figure 51 through Figure 53 show the trend of DIs and PSG values of three test sections (these sections were selected from examples discussed in Figure 41). From Figure 51 through Figure 53 , two observations can be made that reflect trends seen in the DI data.

- The slope of $D I_{J 1}$ in these examples was close to zero, while the slope of $D I_{J 2}$ was positive.
- The slope of $\triangle D I$ and $P S G$ did not always indicate the same direction of curvature.

These initial observations were examined by performing linear regression analysis on $D I_{J_{1}}, D I_{J_{2}}$, $\triangle D I$, and $P S G$ for all test sections.

Figure 53. Graphs. DI and PSG trends using test section 370202.
Intercept of $D I_{J 1}\left(D I_{J 1 i}\right)$, slope of $D I_{J 1}\left(D I_{J_{1 s} s}\right)$, intercept of $D I_{J_{2}}\left(D I_{J_{2 i}}\right)$, and slope of $D I_{J_{2}}\left(D I_{J_{2 s}}\right)$ resulted from regression analysis of DIs at locations J1 and J2. Figure 54 shows the number of test sections for which the slopes of $D I_{J_{1}}$ and $D I_{J_{2}}$ were inversely related (one was positive and one was negative) and for which the slopes of $D I_{J 1}$ and $D I_{J_{2}}$ were the same (either both were positive or both were negative). $D I_{J_{1}}$ and $D I_{J_{2}}$ had an inverse relationship in about half of the evaluated test sections. The average slope of $\Delta D I$ (the difference between $D I_{J_{1}}$ and $D I_{j_{2}}$ ) was much more significant when $D I_{J 1}$ and $D I_{J_{2}}$ were both positive. This significance suggests the relationship between $D I_{J_{1}}$ and $D I_{J_{2}}$ may be relative to each other and not to a slope of zero. In other words, a zero DI value at J 1 or J2 did not necessarily mean that the amount of slab uplift at this FWD test point location was also zero. The use of $\triangle D I$ mitigated this issue because $\Delta D I$ was the difference between DI values.

Source: FHWA.
Figure 54. Graph. Categorizing the regression slope of $D I_{J_{1}}$ and $D I_{y_{2}}$.

Linear regression analysis of $\Delta D I$ yielded an intercept ( $\Delta D I_{i}$ ) and a slope ( $\Delta D I_{s}$ ). Values for each test section can be found in appendix G. Figure 55 and figure 56 compare these $\Delta D I$ regression values to $P S G_{i}$ and $P S G_{s}$ respectively. Like the climate-based PSG regression analysis, FWD testing performed only in the first 10 years after construction was considered for regression analysis. $P S G$ and $D I$ values became highly variable after 10 years and were not useful for trend analysis.

The section-by-section comparisons found that $\Delta D I$ regression values very often did not agree with the trends in PSG regression values. For example, a zero PSG value indicated that no curvature was present in the slab, but $\Delta D I$ often indicated the presence of some slab uplift with either a positive or negative value. Voids, soft soils, liquefaction, and dowel socketing can affect DI ; therefore, it was difficult to directly compare one section to another section. The $\Delta D I$ values were influenced by structural and environmental factors, which needed to be considered when comparing the sections.

Figure 55 shows that the initial curvature of the pavement had more agreement in warm, dry climates than in cool, wet climates. Figure 56 shows the change in curvature over time that, regardless of climate, about half the test sections had $\Delta D I_{s}$ with the same direction of curling as $P S G_{s}$ and about half did not. Test sections in North Carolina were the only exception as $\Delta D I_{s}$ and $P S G_{s}$ agreed with each other more frequently. If PSG was to be used as the baseline for the true direction of curvature, then $\Delta D I_{s}$ was not able to predict the correct curl-and-warp direction by itself because $D I_{J 1}$ and $D I_{J_{2}}$ were weighted equally in the computation $\Delta D I_{s}$. The DI values at the slab corner and slab center need to be weighted differently to predict PSG. Linear regression analysis was performed to predict PSG depending on the base type and other structural factors that may affect curl-and-warp behavior.

Figure 56. Graph. Change over time in curvature direction (up or down) of $\Delta D I_{s}$ versus $P S G_{s}$.

To determine how structural factors influence the interpretation of $\Delta D I$, researchers performed linear regression analysis using the structural factors defined in Table 13 (i.e., slab width, slab length, layer thicknesses, paste volume, flexural strength, and elastic modulus). The analysis also considered the average temperature gradient ( $\Delta T$ ) and regression coefficients (intercept and slope) of $D I_{J_{1}}$ and $D I_{J_{2}}$. The DI at test points J1 (slab center) and J 2 (slab corner) may be interpreted differently depending on base type. Granular and flexible bases are more likely to deform to fit the curvature of a curled or warped slab, while rigid bases are more likely to retain their shape or form their own curvature because of curl and warp.

Table 13. DI analysis: structural design factors for PSG correlation.

| Design Factor | Variable |
| :--- | :---: |
| Average slab width (ft) | $W_{s l a b}$ |
| Average slab length (ft) | $L_{\text {slab }}$ |
| Average layer thickness of PCC (inch) | $h_{P C}$ |
| Average layer thickness of base (inch) | $h_{B}$ |
| Average layer thickness of GB (inch) | $h_{G B}$ |
| Average layer thickness of PATB (inch) | $h_{P A T B}$ |
| Average layer thickness of LCB (inch) | $h_{L C B}$ |
| Average layer thickness of granular subbase (inch) | $h_{G S}$ |
| Average layer thickness of treated subbase (inch) | $h_{T S}$ |
| Estimated PCC paste volume (percent) | $P V$ |
| Estimated PCC flexural strength (ksi) | $F$ |
| Estimated PCC elastic modulus (ksi) | $E$ |
| Average temperature gradient ( $\left.{ }^{\circ} \mathrm{F} / \mathrm{inch}\right)$ | $\Delta T$ |

Figure 58. Equation. Calculation of $\boldsymbol{P S G} \boldsymbol{G}_{\boldsymbol{s}}$ using DI and structural factors.
In terms of base type, the results from these prediction models shared several similarities to the climate-based prediction models developed in climate analysis, which can be found in chapter 8 .

Table 16 shows a summary of residual standard errors, R-squared values, F-statistic values, and $p$-values for each model. The prediction model for $P S G_{i}$ had a better fit in test sections with GBs than in sections with treated bases. In contrast, the prediction model for $P S G_{s}$ had a better fit for treated base test sections than GB test sections.

Table 16. DI analysis: summary of prediction model statistics.

| Model <br> Statistic | GB <br> Base Type | PATB <br> Base Type | LCB <br> Base Type |
| :--- | :---: | :---: | :---: |
| $P S G_{i}$ Model - Residual standard error | 0.4106 | 0.38550 | 0.67190 |
| $P S G_{i}$ Model - Multiple R-squared | 0.7970 | 0.68450 | 0.67190 |
| $P S G_{i}$ Model - Adjusted R-squared | 0.3331 | 0.26380 | -0.07795 |
| $P S G_{i}$ Model - F-statistic | 1.7180 | 1.62700 | 0.89610 |

Figure 59 shows the plots by base type comparing predicted $P S G_{s}$ (from DI regression coefficients and structural factors) and measured $P S G_{s}$ (from profile analysis). The following similarities between this regression analysis and the analysis performed on climatic factors (Figure 46) were determined as follows:

- GB test sections had a good prediction for $P S G_{i}$ but a poor prediction for the $P S G_{s}$.
- PATB test sections had a satisfactory prediction for $P S G_{i}$ and a good prediction for $P S G_{s}$. $P S G_{i}$ in PATB test sections were not very large.
- LCB test sections had a satisfactory prediction for both $P S G_{i}$ and $P S G_{s}$.

-No data.
The results were mixed on which coefficients were most significant for predicting $P S G_{i}$. The thicknesses of treated subbases were a significant factor. Only the test sections located in Kansas and North Carolina ( 31 percent of all selected SPS-2 test sections) had treated subbases with typical thickness between 6 and 8 inches. Whether a test section had a treated subbase had some control over how DI values correlated to PSG. However, this may not necessarily be because of the subbase but possibly related to environmental conditions that Kansas and North Carolina may share. Temperature gradient was significant for test sections with GB and LCB. Paste volume was more significant in PATB sections. The following DI regression values were found to have some significance in all $P S G_{i}$ models but the significance of specific DI coefficients depended on the base type:

- GB test sections were more controlled by the slope and intercept of $D I_{J 1}$.
- PATB test sections were more controlled by intercept of $D I_{J_{1}}, D I_{J_{2}}$, and $\Delta D I$. In other words, the initial DI conditions controlled the prediction of the initial PSG condition.
- LCB test sections were more controlled by the slope and intercept of $D I_{J 2}$.

Most test sections had a $P S G_{i}$ that was close to zero, especially the PATB sections. A few GB and LCB test sections had an initial upward curl. When the slab curls upward, the corners of the slab were expected to rise slightly off the base. Researchers observed the rise on LCB test sections where the $P S G_{i}$ correlated better with the DI at the slab corner. However, on GB test sections, the upward curl correlated better to the DI at the slab center. A large DI at the slab center should be more indicative of a downward curl. Results shows that several test sections began with an upward curl curled downward over time. The GB may have conformed to the
initial upward curl (bowl shape) of the slab, but as the slab curled downward, uplift was created at the slab center.

For predicting $P S G_{s}$, the coefficients that have significance vary considerably depending on the base type. There were low $p$-values for the coefficients of elastic modulus and slab width in the PATB model. The coefficients in other models commonly have slightly higher $p$-values. Slab dimensions (i.e., width, length, and thickness) are significant coefficients just as they were in the climate analysis. The following DI coefficients also had significance, but this could be due to random error because their $p$-values were slightly high:

- GB test sections were more controlled by the slope of $\Delta D I$ and $D I_{J 2}$.
- PATB test sections were more controlled by the slope and intercept of $D I_{J_{1}}$ and the intercept of $\triangle D I$.
- LCB test sections were more controlled by layer thickness, paste volume, and temperature gradient.

Changes in DI at the slab corner indicated slabs curled upward over time or there was a void at the slab edge. Similarly, DI changes at the slab center showed slabs may have curled downward or there was a void under the center of the slab. $\Delta D I$ was also significant because it is a function of DI at the slab center and corner. Test sections with GB curled either upward or downward over time, as shown in Figure 59. The predictive models for $P S G_{s}$ showed that GB test sections were sensitive to the initial DI at the slab center and the change in DI at the slab corner. This indicated some slabs that may have started out curled in one direction might have curled in the opposite direction over time. PATB test sections were more sensitive to the initial DI and the change in DI at only the slab center. PATB test sections; therefore, tended to curl downward creating uplift at the slab center. The $P S G_{s}$ of LCB test sections, on the other hand, did not correlate well to DI values. The LCB test section tended to curl downward over time; therefore, $P S G_{s}$ should have been sensitive to DI at the slab center but DI values were generally random and inconsistent with PSG. It is possible the lack of correlation between DI and PSG was caused by curvature in the LCB.

## RELATING AVERAGE TEMPERATURE GRADIENT AND $\Delta D I$

The relationship between $\Delta D I$ and average temperature gradient ( $\Delta T$ ) can be placed into two main categories: parabolic and linear. Fifty-five percent of the test sections exhibited a parabolic relationship between $\Delta D I$ and average temperature gradient, many of which show negative $\Delta D I$ values corresponding to positive average temperature gradient values. Forty-five percent of the test sections showed a linear relationship, where $\Delta D I$ decreased as average temperature gradient increased.

The value of $\Delta D I$ is the difference between DI values at the slab center and the slab corner. Testing at these two locations usually occurred nonconsecutively; therefore, the temperature gradient at the time of testing was different for the slab center than the slab edge. Because of this difference, an average of these temperature gradients was used for comparison to the $\Delta D I$ value. Figure 60 shows how much temperature gradient can change as the duration of FWD testing increases. Since most FWD testing is completed within 1 to 5 hours, the fluctuation in temperature gradients may cause the DI for a slab to change during FWD testing.

Figure 61 shows the parabolic or linear model that describes the relationship between $\Delta D I$ and temperature gradient can possess very low R-squared values due slab-by-slab fluctuation of temperature gradient and DI during FWD testing.

Source: FHWA.
Figure 60. Graph. Change in temperature gradient with the duration of FWD testing.

Source: FHWA.
Figure 61. Graph. R-squared value of parabolic and linear relationships between $\Delta D I$ and $\Delta T$.

There were linear relationships between $\Delta D I$ and the average temperature gradient in half of the test sections. In these cases, as average temperature gradient increased, $\Delta D I$ typically decreased. Figure 62 shows test section plot with a linear relationship between $\Delta D I$ and $\Delta T$. In this figure,
test section 370201 shows that as the average temperature gradient became positive, $\Delta D I$ became negative. Both a positive $\Delta D I$ and a negative $\Delta T$ indicated that slabs had a downward curl. The R -squared value in this example is 0.059 because of the variation in slabs and the time of testing.

Source: FHWA.
Figure 62. Graph. $\Delta D I$ versus average temperature gradient of section 370201.
The other half of the test sections exhibited a parabolic relationship between $\Delta D I$ and the average temperature gradient. For these test sections, the vertex of the parabola occurred at an average temperature gradient of $-1.5 \pm 1^{\circ} \mathrm{F} /$ inch. Therefore, for an average temperature gradient of -1.5 $\pm 1^{\circ} \mathrm{F} / \mathrm{inch}, \Delta D I$ is at its highest point. As average temperature gradient continued to decrease, there was a slight decrease in $\Delta D I$. This decrease occurred at an average temperature gradient of $-2.5 \pm 1^{\circ} \mathrm{F} /$ inch. To the right of the vertex, as the average temperature gradient became positive, there was a greater decrease in $\Delta D I$. Figure 63 shows test section 040213 , which is an example of this parabolic relationship.

Source: FHWA.
Figure 63. Graph. $\Delta D I$ versus average temperature gradient of section 040213.

For many of the sections that showed a parabolic relationship between average temperature and $\Delta D I$, the vertex often had a positive $\Delta D I$ value, which means the DI at the panel center was greater than the DI at the panel corner. Therefore, the panel was curling downward at a temperature gradient between $-1.5 \pm 1^{\circ} \mathrm{F} /$ inch. These positive $\Delta D I$ values correspond with negative average temperature gradient values. A negative temperature gradient indicated the panel had a higher temperature at the top and a lower temperature on the bottom, meaning the panel would likely curl downward. Figure 64 demonstrates how $\Delta D I$ and $\Delta T$ agreed with each other. This figure also shows how $\Delta D I$ became more unpredictable as $\Delta T$ increased, which was a typical behavior in all test sections with a parabolic relationship.

Source: FHWA.
Figure 64. Graph. $\Delta D I$ versus average temperature gradient of section 390209.
This analysis was not able to conclusively determine why some sections had a linear relationship and others had a parabolic relationship. However, observations suggested the type of relationship between $\Delta D I$ and $\Delta T$ was based on the amount of warping present in the slab during testing. Slabs that had parabolic relationships typically had little curvature (PSG values near zero) and linear relationships were seen more often in slabs that were warped upward or downward. This may be similar to how the relationship between IRI and PSG was not linear at low magnitudes of curl and warp in the PSG analysis.

## CORRELATING PSG AND LEAVE SLAB LTE

LTE is a measurement of the percentage of a load that is transferred from the approach slab to the leave slab through dowels and aggregate interlock. Poor LTE is likely to result in various distresses, such as pumping, corner breaks, and faulting. Some factors that reduce LTE include voids under the slab joint, socketing of dowel bars, and polished aggregates in the aggregate interlock. Figure 65 shows how measurements of LTE typically reduced over time despite the direction of curvature in PSG. The figure illustrates that both PSG and LTE had some variability in their measurement, which was expected because both were affected by seasonal variations in climate; therefore, relative changes in PSG were reflected in relative changes in LTE.

C. Example for test section 370202 .

Figure 65. Graphs. Examples of LTE and PSG measurements over time.
The variability in the PSG trend was a combination of the effects of curling and warping. Warping was controlled by seasonal changes in relative humidity caused by drying shrinkage in the cement paste. In contrast, curling was controlled by seasonal and daily variations in
temperature that caused differential thermal expansion in the aggregate component. LTE was also influenced by seasonal and daily temperature variations; temperature variations that caused thermal expansion to control the effectiveness of aggregate interlock between slabs.

Figure 66 shows the categorization of test sections by the linear regression slope of PSG and LTE (i.e., $P S G_{s}$ and $L T E_{s}$ ) using data from the first 10 years after construction. Approximately half of all test sections had positive PSG slopes and the other half had negative PSG slopes. The average PSG slopes in these categories were between 0.03 and 0.04 . This indicates that in most cases, the change in PSG per year was very subtle. A positive slope meant that slabs in the test section curled downward on average and a negative slope meant they curled upward. When the PSG slope was positive, the number of test sections that had a positive or negative LTE slope was about the same. When the PSG slope was negative, there were more test sections that had a negative LTE slope than sections with a positive LTE slope. LTE does not normally increase over time. When LTE slope was positive, the average gain in LTE was 0.4 percent per year, a very minor increase that may be within the margin of error due to seasonal variations in LTE. A positive LTE slope typically meant that the test section maintained its original LTE value over time. A negative LTE slope indicated that the LTE decreased over time. In cases where LTE slope was negative and PSG slope was positive (downward curling), the average LTE slope was -0.5 percent per year. Compared to the positive LTE slope, this amount of change in LTE was within the margin of error due to seasonal variation and may reflect that in most case the LTE did not reduce over time. However, when both LTE and PSG slope were negative (decreasing LTE and upward curling slabs), the average LTE slope was slightly lower at -1.5 percent per year. As slabs curled upward, voids were potentially created at the uplifted edge. These voids may have contributed to a reduction in LTE.

Source: FHWA.
Figure 66. Graph. Categorizing the regression slope of PSG and LTE.
PSG and LTE did not directly correlate; therefore, linear regression analysis was performed to determine if consideration of structural factors could improve correlation between PSG and LTE.

The following PSG prediction models were developed using $L T E_{i}$ and $L T E_{s}$ (LTE regression intercept and slope using data from the first 10 years after construction) and test section structural factors as defined in Table 13.

Figure 67 and Figure 68 show models for predicting $P S G_{i}$ and $P S G_{s}$ using $L T E_{i}, L T E_{s}$, and structural factors. Table 18 describes the linear regression coefficients in Figure 67 and Table 19 describes the linear regression coefficients in Figure 68.

Figure 68. Equation. Calculation of $\boldsymbol{P S G}_{\boldsymbol{s}}$ using LTE and structural factors.
Table 20 shows statistics of the prediction models for the LTE analysis. Overall, R-squared values ranged from 0.493 to 0.780 and the $p$-values ranged from 0.002 to 0.579 . The best prediction model was the $P S G_{s}$ for PATB test sections. The poorest prediction model was for the $P S G_{s}$ of granular base pavements. The other prediction models had satisfactory results, but the relatively high $p$-values on the LCB prediction models indicated that the correlation likely resulted from random error.

Table 20. LTE analysis: summary of prediction model statistics.

| Model <br> Statistic | GB <br> Base Type | PATB <br> Base Type | LCB <br> Base Type |
| :--- | :---: | :---: | :---: |
| $P S G_{i}$ model—Residual standard error | 0.366 | 0.355 | 0.567 |
| $P S G_{i}$ model—Multiple R-squared | 0.746 | 0.643 | 0.633 |
| $P S G_{i}$ model—Adjusted R-squared | 0.469 | 0.375 | 0.234 |
| $P S G_{i}$ model—F-statistic | 2.695 | 2.400 | 1.584 |
| $P S G_{i}$ model-p-value | 0.056 | 0.052 | 0.227 |
| $P S G_{s}$ model-Residual standard error | 0.108 | 0.034 | 0.073 |
| $P S G_{s}$ model—Multiple R-squared | 0.493 | 0.780 | 0.693 |
| $P S G_{s}$ model—Adjusted R-squared | -0.060 | 0.615 | 0.358 |
| $P S G_{s}$ model—F-statistic | 0.891 | 4.733 | 2.068 |
| $P S G_{s}$ model—p-value | 0.579 | 0.002 | 0.120 |

Figure 69 shows the plots by base type comparing predicted $P S G_{i}$ and $P S G_{s}$ from LTE and structural factors to measured $P S G_{i}$ and $P S G_{s}$ from profile analysis. The following findings were similar to the previous climate and DI analysis:

- GB test sections had a better prediction for the $P S G_{i}$ than $P S G_{s}$.
- PATB sections had a better prediction for the change in curvature than the initial curvature.
- LCB test sections had a satisfactory prediction for both the initial slab curvature and the change in slab.

-No data.
For predicting $P S G_{i}$, coefficients of layer thickness had the lowest $p$-values. These layers typically were granular and treated subbase layers. Test sections with treated subbase were only present in SPS-2 projects in Kansas and North Carolina. Granular subbases were present in test sections in all States, but Washington had particularly thick granular subbase layers (5070 inches). The thickness of the subbase may affect prediction of PSG, but it is also likely that the subbase layer thickness coefficient was classifying projects by the environmental conditions at the sites where subbases were present. Treated subbase thickness had relatively low significance in the model for PATB test sections. Granular subbase thickness did not have significance in the model for LCB test sections. Base thickness did have significance in the LCB model but not in the GB or PATB models for predicting initial curvature, $P S G_{i}$. The following describe the models by base type:

- GB: The most significant coefficients for this model were the thickness of the subbase layers and the PCC layer. The thickness of the GB was not significant. The PCC slab width, elastic modulus, temperature gradient, and paste volume had some minor significance, but this may be the result of random error. The initial LTE had no significance, and the LTE slope value had minor significance. Based on this dataset, LTE did not correlate well to PSG on test sections with GBs.
- PATB: Granular subbase thickness had the lowest $p$-value, but the initial LTE was also significant in predicting the initial PSG. Other factors that had relatively high $p$-values included paste volume, slab width, layer thickness, and temperature gradient.
- LCB: The thickness of treated subbase was the most significant coefficient. The LCB model was the only model for which the thickness of the base layer was also significant. Both the initial LTE and the LTE slope had significance in predicting the initial PSG, which suggests that in test sections with LCB, there might be a relationship between the initial slab curvature and the initial LTE and change in LTE over time.

Some coefficients of layer thickness were also significant for predicting $P S G_{s}$, which is similar to the prediction model for $P S G_{i}$. The layer thickness of granular and treated subbases may be significant because they classified the environmental condition of test sections by the project location where those subbases were present. Treated subbases were found only in North Carolina and Kansas and extremely thick GBs were found only in Washington; therefore, these coefficients may act as indicators of environmental conditions at these project locations. Slab width, $h$, elastic modulus, and paste volume have also shown significance, in addition to layer thickness. Each model for $P S G_{s}$ is described by base type as follows:

- GB: This model showed poor correlation. Most coefficients in this model showed high $p$-values and suggested the correlation may be from random error. The most significant coefficient was slab width, with a $p$-value of 0.287 . The LTE slope might have some relationship with the PSG slope, but the $p$-value for it was slightly too high.
- PATB: This model was better than the models for the other two base types. It showed the PCC elastic modulus and the initial LTE strongly controlled the change in PSG over time. A few other coefficients had minor significance, including slab width, slab thickness, and change in LTE over time.
- LCB: The model LCB pavements were strongly controlled by non-LTE coefficients, including granular subbase thickness, slab thickness, temperature gradient, paste volume, and treated subbase thickness. This model suggests that LTE did not relate to PSG in this dataset of LCB test sections.

## SUMMARY OF FINDINGS

FWD testing provides valuable information on the physical properties of pavements. FWD is typically performed on LTPP test sections every 1 to 6 years. Analyzing these data provided insight into how FWD testing may be affected by the curl and warp of concrete pavements. The analysis was divided into three parts: (1) the development and evaluation of DIs, (2) correlation of DIs to PSG and temperature gradient, and (3) correlation of LTE to PSG.

DIs were expected to express the amount of deflection at an FWD testing point that was not from linear elastic loading of the pavement slab. The DI values were calculated based on regression of three deflection measurements at different load levels. Ninety-nine percent of the regressions performed had R-squared values of 0.98 or greater. Despite the good correlation between deflection and loading, the actual relationship between pavement deflection and loading was nonlinear. The simplification of the linear elastic model may have slightly skewed the DI. Because of this skew, the DIs may not have reflected the actual uplift of the slab at some locations. This nonlinear relationship between pavement deflection and loading explains why DIs can be negative even though the uplift of a slab cannot be a negative value. DIs were not
only the result of the uplift of a slab, but also affected by the reaction from the base or by internal stresses within the slab.

Many sources of variability made clear trends in the relationship between DI and PSG difficult to observe. In addition to the ambiguous interpretation of DI, PSG values were also subject to seasonal variability and they were based on profile testing performed at different times and frequencies than FWD testing. The DI analysis focused on potential factors that may have influenced the relationship between a linear 10-year trend between DI and PSG values. The same approach was used to analyze the relationship between LTE and PSG values because LTE is based on FWD data.

The DI analysis first determined that there was no direct correlation between DI and PSG. The climate analysis established that PSG was predictable based on climatic and structural factors. To avoid biasing the correlation between DI and PSG with climatic data, only structural factors were considered in the DI analysis. The structural factors included base type, layer thickness, PCC slab width, slab length, elastic modulus, modulus of rupture, and paste volume. Temperature gradient was also included because it was based on FWD testing data.

The PSG prediction models using DI values had slightly less error than models based on climatic factors or models based on LTE values. All PSG prediction models had R-squared values between 0.84 and 0.49 , suggesting most models provided a satisfactory fit to actual PSG values. The $p$-value of most coefficients in these models was typically high, but there were a few cases for which coefficients had low $p$-values. Comparing the results from PSG prediction models from the climate analysis, DI analysis, and LTE analysis led to the following observations:

- Models with the lowest correlation between coefficients and PSG predicted the change in PSG over time on test sections with GBs. The R-squared values of these models in the LTE, climate, and DI analyses were $0.49,0.58$, and 0.63 , respectively. There are two possible reasons for this low correlation: (1) the data for these test sections were more unpredictable and subject to higher variability than test sections with treated bases and (2) test sections with GBs were by nature more difficult to predict warping because of physical properties of the unbound material, such as stiffness, erodibility, drainage, swelling, liquefaction, freeze-thaw, and deformation.
- Models with the highest correlation between coefficients and PSG predicted the change in PSG over time for test sections with PATBs. The R-squared values of these models were 0.81 and 0.84 in the climate and DI analyses, respectively. Base type is a major distinguishing feature between models with poor correlation and good correlation; therefore, physical properties of the base are more likely to influence the predictability of PSG over time.
- Models with the second highest correlation between coefficients and PSG predicted the initial PSG for test sections with GBs. The R-squared values of these models were 0.78 and 0.80 in the DI and climate analyses, respectively. Despite the difficulty in predicting the change in PSG over time in GB test sections, the initial curvature assigned to autogenous shrinkage was easier to predict. The base type was the distinguishing feature in the PSG's predictability. The built-in PSG occurred over a short time period; therefore,
material properties that change over time will likely have less influence on the PSG. This could be the reason for a good prediction of initial PSG and a poor prediction of change in PSG.

Change in PSG over time is typically controlled by warping resulting from differential drying shrinkage. Curling was initially thought to provide nonpermanent seasonal variation in the curvature. The most significant coefficient for predicting the change in PSG over time was the elastic modulus (stiffness) of the PCC slab. The second most significant coefficients were the thickness and width of slabs, followed by treated base thickness, initial DI at the slab center, change in LTE over time, paste volume, and granular subbase thickness.

In the case of prediction models for initial PSG, the coefficient with lowest $p$-value (most significance) was typically the average relative humidity. This was followed by the initial LTE, thickness of treated and granular subbases, PCC thickness, intercept value, and average daily difference in relative humidity.

Coefficients that had low significance in predicting the initial PSG include modulus of rupture, most DI coefficients, PCC elastic modulus, and paste volume. Only the modulus of rupture had low significance in both models for predicting initial PSG and change in PSG; however, it is not clear why the significance is low. The significance of most other coefficients typically varied depending on what was being predicted. These variances suggested the mechanism that caused the initial PSG was different from the mechanism that caused the change in PSG.

The thickness of treated and granular subbases was unusually significant in prediction models. Only two projects had treated subbases; one of them had an unusually thick treated granular subbase. Two possible reasons for the significance of these coefficients include the presence of certain subbases that influenced both the initial and change in PSG, which seems unlikely because the base thickness had low significance in predicting PSG and these coefficients are project specific; therefore, there may be unknown environmental, material, or constructionrelated factors present that have coincidentally been classified by the presence of subbases found in these projects.

Aside from base thicknesses, other coefficients with low significance for predicting the change in PSG include the modulus of rupture and slab length. Low significance does not mean the modulus of rupture and slab length coefficients had no effect on the amount of curling due to seasonal cycles, but they were not significant for predicting the yearly change in PSG.

While a formal sensitivity analysis was not performed to determine whether certain factors could be adjusted to improve the correlation in prediction models, in earlier iterations of this analysis, erroneous values were used in the calculation of granular subbase thickness. These erroneous values, however, had improved correlations in some cases. It is possible the inputs used to develop prediction models could be refined further to provide a better fit. Temperature gradient, for example, was found to have a parabolic relationship to DI in about half of all test slabs. Other factors with similar nonlinear relationships could have improved the overall fit of prediction models, which could be an opportunity for a future study.

## CHAPTER 10. ALR

This report presents detailed information about changes in sectionwide roughness using IRI values and slab curl and warp using PSG. The distribution of roughness is an aspect of longitudinal road profiles that relates to functional and structural performance. The ALR may degrade ride quality disproportionately and may indicate the presence of surface defects or surface distress. Per AASHTO R54, ALRs are defined as any region where the IRI averaged over a $25-\mathrm{ft}$ base length is greater than a specified threshold. ${ }^{(24)}$ ALR is generally defined as a range within a pavement section where the roughness profile with a specific base length has a magnitude above a given threshold.

Figure 70 shows the right roughness profile for section 040213 collected 14.2 years after the section opened to traffic. This roughness profile uses an averaging base length of 25 ft . As such, each point in the roughness profile is the IRI averaged over a 25 - ft interval, which has boundaries 12.5 ft upstream and 12.5 ft downstream. The figure also marks a threshold of 150 inches/mi using a horizontal line.

With a base length of 25 ft and a threshold of 150 inches $/ \mathrm{mi}$, this profile has seven ALRs with an area of 157.9 ft . The largest ALR with the highest peaks appear at 36.6-53.5, 121.2-174.6, $177.0-206.7$, and $310.2-345.5 \mathrm{ft}$. These ALRs correspond to locations where the profiler passed over wide longitudinal cracks in the right wheel path. The remaining areas do not correspond to any known surface distress; rather, they are areas where the severity of upward slab curl exacerbated the roughness sufficiently to raise the roughness profile above 150 inches $/ \mathrm{mi}$. These ALRs may grow or decrease in range and severity with seasonal or diurnal changes in slab curl. The ALR at 247.8-249.0 ft, which has a peak roughness just above 150 inches $/ \mathrm{mi}$, will have a roughness level below the threshold if the severity of upward curl decreases. Alternatively, additional ALRs may appear if the severity of upward curl increases.

Source: FHWA.
Figure 70. Graph. Right roughness profile of section 040213 at 14.2 years.
Figure 71 demonstrates short-term changes in ALRs caused by changes in curl and warp. The figure marks ALRs in the right wheel path for each of five repeat passes over section 040213 in diurnal visits conducted over four seasons. These data were collected 9.9 to 10.7 years after the
open-to-traffic date. For each pass, figure 71 marks any area where the IRI is above 160 inches $/ \mathrm{mi}$ in the right roughness profile for a base length of 25 ft . Two items in the figure stand out. First, the location and extent of the ALR is similar but not exact for all five repeat passes within each set. Second, the nominal level of ALR exhibits seasonal and diurnal changes, which are attributed to curl and warp.

Source: FHWA.
Figure 71. Graph. Section 040213 ALR for seasonal, diurnal, and repeated passes.
Figure 72 summarizes the diurnal and seasonal changes in ALR on the right side of section 040213. The figure shows the average extent of ALR for each of the 16 visits. Note that in August 2003 and June 2004, the extent of ALRs is greater than in December 2003 and March 2004. The ground under the pavement is warmer compared to December 2003 and March 2004, which promoted upward curling. Also, within each seasonal group, the total extent of ALR is highest in the early morning hours and lowest in midafternoon because the upward slab curl is the most severe before sunrise and the least severe at midday.

Source: FHWA.
Figure 72. Graph. Section 040213 average ALR for seasonal and diurnal visits.
Figure 73 demonstrates long-term changes in ALR on section 040213 using a base length of 25 ft and a threshold of 160 inches $/ \mathrm{mi}$. The figure marks ALR for each repeat measurement over the section over the monitoring history for LTPP. The figure also lists the age of the test section relative to the date the section opened to traffic. The figure shows a growth in ALR over the first 16 years, which includes an increase in the extent of ALR as longitudinal cracking appears in the right wheel path. However, the trend is most likely confounded by seasonal and diurnal changes in curl and warp as the extent of ALR for a specific visit is affected by environmental conditions at the time. The ALR that is registered in areas with longitudinal cracking also depends on the transverse positioning of the profiler within the lane.

Figure 70 through Figure 73 provide a detailed analysis of ALR for the right side of section 040213. The LTPP and FHWA profile datasets offer an unusual opportunity to examine ALR of jointed concrete pavements in detail. For this study, the longitudinal profiles were synchronized throughout their entire monitoring period, such that their starting locations and accumulation of longitudinal distance is consistent beyond what was possible with careful field procedures. These data were used to study short- and long-term changes in ALR of the 83 test sections included in this research.

The study also included an examination of the extent and severity of ALR repeatability, which was performed using well-synchronized data. The data were accurately aligned; therefore, changes in ALR are attributed to tracking variations and other sources of profile-measurement uncertainty not related to measurement of longitudinal distance. Variations in ALR location were also addressed using unsynchronized measurements.

Source: FHWA.
Figure 73. Graph. ALRs long-term changes of section 040213.

Appendix J provides results of ALR analysis of several test sections. Like section 040213, many test sections included short-term variations in ALR caused by changes in curl and warp. All test sections exhibited long-term changes in ALR. These effects included long-term growth in roughness, the confounding effects of changes in curl and warp, increased roughness at locations with distress, and changes in roughness caused by maintenance. Overall, the analysis showed that the potential influence of curl and warp must be considered when interpreting ALR on jointed concrete pavements. Timing and prevailing environmental conditions must be reported with ALR measurements and considered when interpreting the results or comparing ALR extent and severity.

Appendix J describes other effects of practical concern, including the following:

- ALR depends on index type. For example, using MRI, which is the average of the left and right IRI, in place of individual wheel tracks moderates the most extreme areas of roughness. Using HRI, which is based on averaging the left and right profile before computing the roughness, universally reduces ALR.
- Roughness threshold strongly affects ALR. ALR increases as the threshold value decreases. When the average roughness approaches the ALR threshold, evaluation of ALR becomes less meaningful, and a threshold proportional to the sectionwide average may be more useful for some applications.
- Base length affects the severity of roughness. As base length decreases, peak roughness values grow in severity and highly localized features are easier to pinpoint. However, a base length lower than 25 ft may fail to capture the entire contribution to roughness of a localized feature.
- Severity of an ALR is as important as its extent. ALR with the same extent included a wide range of peak values. Further, several ALR were detected that barely exceeded the threshold or included very low extent. For some applications, an index is proposed that quantifies the extent and severity of ALR.
- ALR length and severity vary more widely than IRI between repeat passes. Several instances were observed where repeated passes were not needed to obtain an accurate measurement of overall IRI, but multiple passes were needed to assess ALR length and severity.

## CHAPTER 11. CONCLUSIONS AND RECOMMENDATIONS

Throughout this study, researchers learned what could-and in some cases could not-be quantified or related to curl and warp on jointed concrete pavements. Key findings regarding the various analysis efforts are summarized in the following sections, and some promising areas for future research are identified.

This research demonstrated detailed analyses of road profiles for detection of jointed concrete curl and warp, changes in curl and warp, and estimation of the influence of curl and warp on the IRI. The research examined the relationship between the IRI and curl and warp quantified using the average PSG over the slabs within a test section, which was done to quantify cyclic and long-term changes in curl and warp and corresponding changes in IRI. The report demonstrates the use of this framework to quantify the effect of curl and warp on the IRI of 83 LTPP test sections, including long- and short-term changes and spatial variation within a test section.

The research sought to estimate the portion of roughness from sources other than curl and warp (i.e., background roughness) using a linear fit between observations of IRI versus PSG over the short term (e.g., diurnal and seasonal changes) and extrapolation to a condition with no curl. Theoretical modeling combined with simulations of random roughness mixed with idealized profiles of curl and warp showed that a linear fit was not appropriate for extrapolation.

An alternative method was proposed based on the assumption that the square of the total roughness was approximated by the sum of the square of background roughness and the square of the roughness caused by curl and warp. Fitting this model to data for individual test sections quantified the influence of curl and warp on the IRI for test sections where large changes in curl and warp were present. However, the PSG-IRI relationship could not be generalized because the PSG-IRI relationship for individual test sections was not consistent enough to justify using the fitted model from one test section to infer the effects of curl and warp on roughness of another test section.

Seasonal and diurnal measurement of jointed concrete test sections is recommended for test sections that require quantifying curl and warp. The diurnal measurements should include four series of passes:

1. Predawn, preferably just before sunrise or when air temperature is at a minimum.
2. At least 2 hours after sunrise.
3. Late afternoon, preferably after solar radiation has maximized for the afternoon and when air temperature is at a maximum.
4. After sunset.

Whenever possible, these measurements should be conducted on a clear day to maximize solar radiation to the pavement surface. The timing of seasonal measurements should favor extremes in daily average solar radiation and extremes in the expected temperature and moisture at the slab underside.

In support of the curl-and-warp analysis, the research demonstrated a methodology for selecting five repeat passes from a larger group of raw profile measurements based on mutual
cross-correlation of IRI-filtered profile traces. This methodology is proposed for any application that emphasizes the effect of specific profile features on the IRI and the distribution of roughness within a test section.

The research also applied an algorithm for isolating the location of transverse joints by identifying narrow downward spikes that appear with the expected spacing. The algorithm is the most successful when repeat profile measurements are available over the same test sections and when narrow downward spikes at the joints are not eliminated from the stored profile by lowpass filtering. Researchers recommend that profile measurements collected for the study of curl and warp include at least three repeat passes for every measurement visit. Further, measurement protocols should include specification of height-sensor footprint, low-pass filtering, and data-recording intervals that facilitate joint finding without introducing spurious (i.e., aliased) short-wavelength content into the profile.

A direct correlation between PSG and climatic factors-such as average temperature and relative humidity-could not be established. However, the following general observations can be made based on the analysis:

- Base type had influence on the correlation of climatic factors to PSG.
- Humidity had the effect on the initial pavement curvature.
- Stiffness of the PCC affected the PSG.
- Correlation with PSG improved with more-refined climate factors.

Recommendations for further investigation of the correlation between climate and PSG include:

- Consider climatic factor that describes seasonal variation.
- Factor the climate during profile testing into correlation analysis.
- Explore nonlinear relationships between climatic factors and PSG.

DI and LTE are parameters derived from FWD testing and were considered to have potential as predictors of PSG and the curl state of the slab. DI and LTE was computed and compared to PSG but were found not to have a correlation. Additionally, DI values at various FWD test points and the relative difference between these DI values were also evaluated and found not to have a correlation to PSG. Structural design factors, such as layer thicknesses, base type, slab dimensions, and paste volume were included in the correlation analysis as coefficients in the regression models developed by researchers. While these models showed good R-squared values, the number of degrees of freedom was low, and these models required additional data to validate. The models did indicate, however, that FWD data alone were not sufficient to compute PSG or evaluate curl state.

The FWD analysis lacked enough established knowledge on the mechanisms affecting curl-andwarp behavior. Researchers made assumptions on what factors were of potential importance to curl and warp and how to compute and interpret these factors. The curl-and-warp indices, such as PSG, DI, and LTE, were also subject to interpretation without sufficient means to validate the interpretation. Curl-and-warp indices varied; therefore, in the analysis, trends were generalized to develop correlations. This generalization reduced the size of the dataset and consequently the degree of freedom in correlations.

Findings from the FWD analysis include the following:

- DI could be developed using LTPP FWD data.
- Interpretation of DI was subject to FWD testing location, curl state of the slab, the base type, and other structural factors.
- Direct relationships between averages of DI and PSG could not be established.
- Change in curl was more difficult to correlate in test sections with GBs than test sections with treated bases.
- Structural properties of the slab influenced the correlation between DI and PSG.
- Unknown factors specific to the site location may have influenced the correlation between DI and PSG or LTE and PSG.

The FWD analysis was not able to establish a correlation between DI and PSG, but the analysis showed that a relationship could potentially exist. Recommendations based on this analysis for further investigation include the following:

- Correlation between $\Delta D I$ and $z_{0}$.
- Nonlinear relationship between DI, LTE, and PSG.
- Slab-by-slab analysis or site-specific analysis on the correlation between DI and PSG.
- Sensitivity analysis on parameters that affect the correlation between DI and PSG.

The potential influence of curl and warp was shown to affect the interpretation of ALR on jointed concrete pavements. Timing and prevailing environmental conditions must be reported with ALR measurements and considered when interpreting the results or comparing ALR extent and severity. Other practical concerns regarding the interpretation of ALRs include the following:

- ALR's dependence on index type.
- Effects of roughness threshold on ALR.
- Effects of base length on the severity of roughness.
- Importance of the severity of ALR compared to the extent of ALR.

## APPENDIX A. LITERATURE REVIEW

## INTRODUCTION

This appendix provides a literature review related to experimental determination of jointedconcrete pavement curl and warp using pavement-surface elevation measurements. Separate discussions are provided for various types of measurement technology, but each discussion emphasizes techniques for quantifying curl and warp using field measurements. Many of the cited references also describe background and research findings relevant to a pavement's response to moisture, thermal, and applied loads not described in this appendix.

## CURL-AND-WARP MEASUREMENT

## Graphical Demonstration

Early studies of jointed-concrete behavior used plots of responses from roughness devices measured along longitudinal tracks to graphically demonstrate curl and warp.

Stanton demonstrated seasonal and diurnal changes in profilograph traces measured on various experimental in-service jointed-concrete pavements in California. ${ }^{(25)}$ Stanton noted "the difference in curvature between morning and afternoon in warm weather and the decreased curvature in the damp cool weather of the rainy season." Hveem showed seasonal, diurnal, and early-age changes to profilograph traces; sensitivity of behavior to soil type; and long-term changes in profilograph traces on the same experimental pavements. ${ }^{(26-28)}$ Tremper and Spellman showed profilograph traces from a later study of concrete shrinkage due to moisture loss and identified curl graphically as shown in figure 74. ${ }^{(29)}$

©1963 Tremper and Spellman.
Figure 74. Graph. Representation of curling using a profilograph trace. ${ }^{(29)}$
Moyer showed traces from a response-type road-roughness measurement system for a segment of road that was "badly warped at the joints." ${ }^{(30)}$ Housel demonstrated seasonal changes in in-service pavements caused by "curling at the joints combined with frost action in the granular base" using traces measured by a truck-mounted profilograph. ${ }^{(31)}$

## Direct Elevation Measurement

Several studies monitored the curl and warp of in-service test pavements by directly measuring elevation changes at critical locations on selected slabs. The instrumentation included a surveyor's rod and level, ${ }^{(32,33)}$ dial gauges, ${ }^{(34-37)}$ slip-pin deflectometers, ${ }^{(38,39)}$ multidepth deflectometers, ${ }^{(40,41)}$ or linear variable differential transformers. ${ }^{(42-45)}$

Evans and Drake cited the difference between elevation at joints and slab midpoints as a measure of warping, and the State Highway Commission of Kansas defined "warping factor"
similarly. ${ }^{(32,33)}$ Spellman, Stoker, and Neal described the measurement of vertical "movements of slab corners to temperature and moisture changes (curl)."(39)

Armaghani, Larsen, and Smith presented slab center, edge, and corner deflections over a 48-hour cycle for comparison to slab temperature and temperature differential. ${ }^{(42)}$ Goldsberry presented slab center, edge, and corner deflections for comparison to thermal loading over several diurnal cycles for multiple seasons. ${ }^{(43)}$ Poblete et al. compared changes in slab corner elevations, which were expressed as uplift, to changes in thermal gradient over diurnal cycles in multiple seasons. ${ }^{(44)}$ Jeong and Zollinger demonstrated the difference between two curing methods on early-age slab behavior through the first seven diurnal cycles by comparing vertical corner displacement to measurements of dowel-bar bending moment and slab material strain. ${ }^{(36)}$ Rao and Roesler and Rao presented changes in edge and corner deflection over 24 hours. ${ }^{(41,46)}$ These studies examined the behavior of instrumented slabs under changes in thermal loading as a basis for explaining behavior under load.

Researchers compared slab deformation to thermal loading using values of curl calculated from measured elevations at critical locations. Lowrie and Nowlen presented "changes in curl" using averaged corner and edge deflections over multiple test slabs. ${ }^{(38)}$ Ardani reported values of curl measured every 30 minutes from early morning until late afternoon, which were defined as the difference in elevation between the corners and slab center. ${ }^{(37)} \mathrm{Yu}$ et al. defined curl as the deflection at slab edges and slab corners relative to the slab center. ${ }^{(35)}$ Values were reported for comparison to temperature gradient over two diurnal cycles.

## Inclinometer-Based Slab Profiles

Teller and Sutherland used a precision clinometer to measure deflections caused by temperature warping and displayed deflection profiles along slab edges and slab longitudinal and transverse centerlines. ${ }^{(47,48)}$ Several modern studies, which are cited in this section, monitored the curl and warp of in-service jointed-concrete pavements using low-speed, inclinometer-based profiles along key lines over selected slabs. In these studies, profiles of relative elevation versus position were collected diagonally and along transverse edges and longitudinal edges. In a few cases, roughness for longitudinal profiles were reported in terms of the IRI to examine early-age behavior or changes at various times of day. ${ }^{(49-51)}$ Curl and warp was typically quantified by direct analysis of measured profiles and related to measurements of slab temperature at various depths, material strain, or other quantities pertinent to structural response.

Rao et al. emphasized early-age and long-term causes of slab deformation and, using profiles collected along slab diagonals, characterized curl as the elevation difference between slab corners and slab center. ${ }^{(52)}$

In some cases, selected locations on in-service pavements were monitored to explain premature cracking. Hansen et al. applied a second-order curve fit to profiles measured along longitudinal tracks and reported edge-to-center elevation difference from the best-fit curve. ${ }^{(53)} \mathrm{Yu}$ and Khazanovich and Beckemeyer, Khazanovich, and Yu measured profiles along longitudinal slab edges and applied a quadratic fit to the profiles after "adjustment for longitudinal slope." ${ }^{\text {"(45,54) }} \mathrm{Yu}$
and Khazanovich and Beckemeyer, Khazanovich, and Yu defined the amount of curling as the difference between vertical deflections at the corners to deflection at the slab center. All three studies applied the curve fit as a way to eliminate the effect of surface irregularities on the results.

Vandenbossche measured profiles along transverse edges, longitudinal edges, and a diagonal of selected slabs at several test sites. ${ }^{(55)}$ In the description of analysis methods, Vandenbossche observed that slab profiles "contained the geometric pavement slope and surface irregularities." Analysis of slab profiles included a zeroing procedure to mitigate the effects of slope. Each profile was adjusted by subtracting the profile measured along the same track under specific environmental conditions. Curvature ( $\kappa$ ) was approximated from the resulting displacement profiles using a second-order curve fit, as shown in figure 75 and figure 76.

$$
y(x)=A x^{2}+B x+C
$$

Figure 75. Equation. Second-order curve fit.

$$
\kappa=\frac{\frac{\partial^{2} y}{\partial x^{2}}}{\left[1+\left(\frac{\partial y}{\partial x}\right)^{2}\right]^{3 / 2}}=\frac{2 A}{\left[1+(2 A x+B)^{2}\right]}
$$

Figure 76. Equation. Curvature derived from a second-order curve fit.
In figure $75, y(\mathrm{x})$ is the fitted displacement profile as a function of distance along the slab diagonal; $A, B$, and $C$ are fitted coefficients. Figure 76 shows that curvature derived from a second-order polynomial is not constant across the entire slab. All reported curvature values, however, were less than $0.00061 / \mathrm{ft}$ and the longest test slab was 24 ft . For these parameters, the curvature varies across the fitted curve by less than 0.06 percent, and curvature may be estimated solely based on $A$.

The studies by Vandenbossche included three technical observations with important implications to quantifying curl and warp from measured longitudinal profile. The observations include the following:

- Using a single parameter to characterize curl was advantageous if it could be justified.
- "Identifying a single parameter that can characterize the measured profile, or slab shape, is beneficial when making comparisons for a range of temperature conditions between cells and within cells. The parameter chosen to characterize the shape of the slab was curvature. ${ }^{\text {. }}$ (55)
- Predicting measured curvature depended on radius of relative stiffness and slab length, in addition to thermal loading.
- Using a curve fit over the entire length of the slab profile achieved satisfactory results, but curvature may vary within a given slab because of the influence of gravity and load-transfer devices.

In a study of early-age behavior, Wells, Phillips, and Vandenbossche monitored selected slab groups with and without dowel and tie bars for the first 72 hours after construction. ${ }^{(56)}$ This study used processing techniques described by Vandenbossche and quantified slab curvature using the value 1 ft into the slab from the edge. ${ }^{(55)}$ Subsequently, Asbahan and Vandenbossche monitored the same slabs over 2 years to quantify the relative influence of temperature gradient, moisture gradient, and restraint at the joints on slab deformation. ${ }^{(57)}$ This study applied the zeroing procedure previously described and quantified curvature using the second derivative of the fitted second-order curve (i.e., $2 A$ from figure 76).

Kim monitored selected slab groups on two newly constructed pavements for 7 days following construction. ${ }^{(58)}$ The study included measuring profiles along diagonals and transverse edges and reported curvature using Vandenbossche's analysis procedure for profiles along diagonals and transverse edges. Ceylan et al. characterized slab deformation in related work from the same field sites using the relative corner-to-center elevation changes from profiles measured along slab diagonals. ${ }^{(50,59)}$

Chen, Nassiri, and Umeyer monitored the deformation of several transverse profiles on five test sections that had been in service for 24 years or more and processed the profiles using a secondorder curve fit. ${ }^{(60)}$ Slab deformation was quantified using the fitted polynomial in two ways: differential deflection between the edges and the center of the slab and curvature estimated using the second derivative.

## Custom Devices

Early studies of slab warp used custom mechanical devices to record the movement of slab edges relative to a fixed external reference over time or the elevation at transverse joints relative to the slab interior. ${ }^{(61,62)}$ Ceylan et al. proposed a low-cost device for the measurement of slab-deflection profiles along a selected line using a stretched wire and either a custom gauge block or a digital depth gauge to measure the gap to the slab surface at various locations along the wire. ${ }^{(63)}$

Lederle, Lothschutz, and Hiller analyzed transverse profiles measured at multiple longitudinal positions on several instrumented test slabs at the MnROAD research facility using the Automated Laser Profile System 2. ${ }^{(64)}$ The system includes a laser that sweeps along a long rigid beam and collects a relative profile along a selected line. Lederle quantified curl and warp by associating properties of the measured transverse profiles with surface profiles predicted by ISLAB2000 for differences in temperature across the depth of the slab. ${ }^{(65)}$ This association produced an empirical estimate of the curl and warp of each measured profile regarding the temperature difference in the predicted profile that produced the best match. After removing the prevailing linear trend (i.e., cross slope) and extraneous points from each transverse profile, researchers used the following three methods of relating measured and predicted profiles:

- Polynomial Curvature Method: A polynomial curve fit was applied to predicted and measured profiles, which were associated with a predicted counterpart based on curvature versus distance across the slab derived from the fitted polynomial.
- $\Delta h$ Method: Measured profiles were associated with a predicted counterpart based on the difference between the slab midpoint and the edges.
- Minimum Error Method: A polynomial curve fit was applied to the measured profiles, which were associated with a predicted counterpart based on a direct fit to the predicted profiles.

Lederle found that agreement between the model and measured profiles was better at the slab center than near the joints because of the restraint placed on vertical movement caused by friction at joints between other slabs or shoulders. ${ }^{(65)}$ The Polynomial Curvature Method and Minimum Error Method were each applied five times using polynomial fits with orders of two through six. The analysis did not produce consistent results for various polynomial orders, and the results for lower-order polynomials were deemed more realistic and more physically relevant. The inconsistency in results for higher-order polynomials illustrates the potential confounding influence of roughness in measured profiles (i.e., curvature and curvature changes) unrelated to slab curl and warp and the importance of fitting the measured profiles directly to an assumed function that corresponds to a structural model of slab deformation.

Ceylan et al. measured curling and warping of slabs on six in-service pavements in Iowa at various times of day using LiDAR scans. ${ }^{(66)}$ The LiDAR scans produced point clouds, which were processed to produce three-dimensional surface profiles for each test slab. Surface profiles were fitted to a general bivariate quadratic function (i.e., elevation was cast as a second-order function of transverse and longitudinal position). Curling and warping was reported in terms of relative deflection for two-dimensional slices along transverse slab edges, longitudinal slab edges, and the two slab diagonals that connect the corners. Relative deflection along each slice was defined as the difference between the fitted profile and a reference line connecting the two ends.

## Inertial Profilers

Darlington and Milliman envisioned "a study of 24-hour slab movement recording actual slab curling" as an application of inertial profilers early in their adoption for use in pavement-network management. ${ }^{(67)}$ Some researchers demonstrated the effect of curl and warp on road profiles using filtered elevation plots and power spectral density plots. (See references 68 through 73.) Other research studies have attributed changes in IRI measured by inertial profilers to changes in curl and warp over daily and seasonal cycles or used changes in IRI measured by inertial profilers to investigate early-age behavior. ${ }^{(70,73,74)}$ Byrum and Sixbey et al. first proposed algorithms for directly quantifying slab curl and warp using inertial profile measurements. ${ }^{(75,76)}$ This section describes several proposed methods for quantifying curl and warp using inertial profiler measurements.

## Byrum Curvature Index

Byrum proposed and demonstrated a curvature index (CI) using high-speed inertial profile measurements collected for the LTPP study on GPS-3 and GPS-4 test sections. ${ }^{(77,78)}$ CI combines discrete curvature estimates calculated from as shown in the equation in Figure 77.

$$
\text { curvature }_{n}=\frac{\text { slope }_{n+i}-\text { slope }_{n}}{x_{n+i}-x_{n}}, \text { slope }_{n}=\frac{y_{n+i}-y_{n}}{x_{n+i}-x_{n}}
$$

Figure 77. Equation. Discrete curvature estimates.

In Figure 77, $y$ and $x$ are the values of profile elevation and longitudinal distance, respectively, at sample points indicted by the subscripts. These expressions reduce algebraically to a form related to midchord deviation and calculation of vertical acceleration from a profile corresponding to a particular interval (i.e., base length). ${ }^{(79,80)}$

In figure $78, \Delta x$ is the profile recording interval, $i \Delta x$ is the interval over which slope is calculated, and curvature $_{n}$ is a three-point estimate of curvature for the corresponding interval.

$$
\text { curvature }_{n}=\frac{y_{n+2 i}-2 y_{n+i}+y_{n}}{(i \Delta x)^{2}}
$$

## Figure 78. Equation. Discrete curvature estimates, constant interval. ${ }^{(77)}$

When CI was first proposed, LTPP profile data were stored at a sample spacing of 6 inches, which determined the values of interval available for computing curvature estimates.

The overall value of CI for a wheel path included a sum of the average curvature estimates calculated over intervals of 6,24 , and 48 inches (i.e., for $i=1,4$, and 8 ). Byrum recognized the potential variation in curvature within long slabs:

One complication in the processing is related to long slab behavior. In this case, the portion of the slab near a joint would have curvature. However, the middle portion of the slab remains flat because of physical and geometric confinement. ${ }^{(75)}$

As such, CI also included additional terms that averaged the 6-inch interval curvature estimates for approach and leave areas within 15 ft of joints or cracks.

Byrum isolated slabs from joints and cracks using a curvature-variation threshold. Points within the profile with relatively high levels of curvature were marked as imperfections, and the areas within 2 ft of imperfections were excluded from the calculation of CI. This approach for detecting joints and cracks was subsequently applied in studies of other behaviors in jointed-concrete pavements, such as rocking and pumping and faulting. ${ }^{(81,82)}$

Byrum demonstrated a model that correlated to the IRI of a $500-\mathrm{ft}$-long profile to a linear combination of CI, the number of imperfections found, the average severity of the imperfections, the SD of curvature estimates with 6- and 48-inch intervals and the average curvature estimate with a 48-inch interval. ${ }^{(77)}$ The model predicted IRI with a standard error of 9.75 inches $/ \mathrm{mi}$.

Byrum later compared several methods of quantifying slab curvature, including three-point curvature estimates, polynomial curve fits, and fitting to an assumed slab profile. ${ }^{(83)}$ The comparison included a detailed description of the Byrum Curvature Index ( BCI ) method. In addition to CI and the underlying curvature estimates, the BCI method includes the report of the average, SD, and standard error for a suite of curvature estimates using intervals of 6 through 48 inches (i.e., $i=1$ through 8 ), a companion set of estimates taken from the profile after the application of a cubic spline filter, and several combinations thereof aggregated for all points within slab boundaries, and within joint-and-crack approach and leave areas.

The comparison included three important observations that translate to other methods of processing profile data to obtain curvature estimates. First, analysis of many slabs over a uniform pavement segment is advantageous because using many slabs reduces variations in curvature estimates caused by confounding variations, such as other sources of roughness. Second, fitting a profile over the length of a slab to an assumed shape may fail to accurately capture an estimate of slope at the slab ends. Third, an algebraic relationship exists between many of the prevailing choices for quantifying slab curl from profile (e.g., center versus edge deformation, differences in slope at slab ends, polynomial curve fits, and fitting to a structural model).

## Curve Fitting

Sixbey et al. analyzed profiles of 65 lane-miles of in-service jointed concrete with premature transverse cracking. ${ }^{(76)}$ Profiles were collected in four passes on the same day, starting in the early morning and ending in the early evening. The research characterized curvature of individual slab profiles using the maximum deformation. The profile-analysis procedure normalized the measured traces into a deformation profile by removing the trend along the slab. This procedure applied a third-order fit to slab-wide profiles and removed a linear trend from the fitted and measured profiles. From the graphical demonstration, plots appeared to show that both fitted and measured profiles were adjusted equally, such that values of zero deformation would appear in the fitted profile at the slab boundaries. Maximum deformation was read from the measured deformation profile at the location where the fitted deformation profile had the largest absolute value.

The work by Sixbey et al. applied curve fitting to reduce the sensitivity of the process to irregularities within each slab. ${ }^{(76)}$ In a subsequent description of the work by Sixbey et al., Gagarin and Mekemson explained that "the curvature of the surface profile is not necessarily equivalent to slab curvature," and concluded that for individual slabs, the relevant measure was changes in deformation. ${ }^{(84)}$ Sixbey et al. characterized the overall behavior of the pavement using the distribution of maximum deformation values for all slabs at a given time and by observing changes throughout the day. ${ }^{(76)}$

Sixbey et al. and Gagarin and Mekemson did not provide details of the procedure for identifying the boundaries of each slab. ${ }^{(76,84)}$ However, researchers recommended using a recording interval 0.2 inches or shorter. Gagarin and Mekemson cited the need to overcome inconsistencies in the measurement of longitudinal distance between multiple runs over the same pavement section. ${ }^{(84)}$

## Fitting to an Assumed Slab Profile

Chang et al. studied seasonal and diurnal profile changes in 19 test sections and diurnal profile changes in 19 additional test sections throughout the United States. Diurnal testing included repeated profile measurements collected during four time periods throughout a 24-hour cycle: early morning, midmorning, early afternoon, and late afternoon. Seasonal testing required diurnal testing once per season yearly. ${ }^{(85)}$

Chang et al. quantified the level of curl and warp in measured profiles by fitting profiles of individual slabs to an assumed shape predicted by the Westergaard equation. ${ }^{(3,20)}$ The

Westergaard equation predicts vertical deformation caused by a constant strain gradient throughout the depth of a slab using structural properties, $b, l$, and $\mu$.

In the procedure used in Chang et al., researchers isolated individual slab profiles by searching for narrow spikes that appeared in the profiles at the joints. This procedure depended on the availability of up to 10 repeat profile measurements collected at each visit and data collected with a narrow height-sensor footprint (i.e., a point laser) and recorded at short intervals (i.e., 0.25 inches). Slab profiles were preprocessed by eliminating a length of profile not exceeding 2 inches at each end and by removing the linear trend.

The fitting procedure, show in in Figure 79, sought a scale factor that produced the best fit between the measured profile and the assumed slab shape.

$$
z(x)=-z_{0} f(x, b, l)
$$

## Figure 79. Equation. Slab profile fitting function.

In the equation in Figure $79, z(x)$ is the fitted displacement function, and $x$ is the distance along the slab with its origin at the slab center. The function $f$ defines the shape of the slab. It is symmetric about the slab center with a value of one at the slab ends. The fitted scale factor is the uplift at the slab ends $\left(z_{0}\right)$ in the fitted function. Results were expressed in terms of the strain gradient required to deform a slab into measured shape, as shown in the equation in Figure 80.

$$
P S G=-z_{0} /(1+\mu) l^{2}
$$

Figure 80. Equation. PSG.
In Figure 80, PSG is measured in units of strain per inch of depth, proportional to magnitude of deformation.

Chang et al. reported the level of curl and warp for slabs within a given road segment in terms of the distribution of PSG values and related changes in HRI for the measured profiles to the average PSG. ${ }^{(3,6)}$ Chang et al. reported diurnal changes in HRI as high as 40 inches/mi. ${ }^{(3)}$ Chang et al. observed that for test sections with large changes in PSG, a strong linear relationship existed between HRI and average PSG and demonstrated extrapolation of the linear fit for estimating the HRI that would exist without slab curl.

Karamihas and Senn applied the method to profiles from the LTPP SPS-2 site in Arizona over the first 16 years of its monitoring history. ${ }^{(12)}$ The study demonstrated a close linear relationship between IRI and average PSG for low-strength sections in which large diurnal and seasonal changes in IRI were observed but not for high-strength sections in which changes in IRI were small. For the low-strength sections, linear regression produced standard estimate of error values ranging from 1.19 to 4.64 inches $/ \mathrm{mi}$.

Ruiz et al. applied the method to diagnose the cause of premature slab cracking to in-service pavements in Bolivia. ${ }^{(86)}$ The study examined variations in PSG within a test section and changes in PSG between profiles measured in the morning and afternoon. Merritt et al. applied the
method to investigate undesirable roughness of a jointed-concrete pavement in Colorado. ${ }^{(87)}$ The study included diurnal profile measurements in February and August of the same year and confirmed the presence of curl in pavements in both directions. The results included changes in HRI of more than 20 inches $/ \mathrm{mi}$ on some test segments and attributed up to 40 inches $/ \mathrm{mi}$ to slab curl in profile collected in the early morning.

## Profile Decomposition

Siddique proposed the separation of a curled profile from components unrelated to curl using a fast Fourier transform algorithm. Siddique attributed roughness at wavelengths equal to the slab length and integer fractions of the slab length (e.g., a half, a third) to slab curl. ${ }^{(88)}$ The fast Fourier transform algorithm was applied to the measured profile. The Fourier coefficients were split into two sets: one for wavenumbers that correspond to the slab length and upper harmonics and another for the remaining wavenumbers. An inverse Fourier transform produces a separate profile for each set of coefficients. The effects of curling were reported for the reduction in the IRI of the profile without the components associated with curl relative to the IRI of the original profile. Siddique provides an example with 9 -percent reduction in the IRI when the curling contribution was removed.

Adu-Gyamfi, Attoh-Okine, and Ayenu-Prah proposed using the Hilbert-Huang Transform (HHT) as a tool for characterizing road roughness using measured profiles. ${ }^{(89)}$ The HHT includes decomposition of profiles into intrinsic mode functions (IMFs). Unlike the Fourier transform, shapes of the IMFs depend empirically on the properties of the measured signal. The HHT is best suited for applications for which the signal under study includes changes in the severity of the measured fluctuations or changes in the contributing frequencies.

Gagarin et al. illustrated the use of the HHT as a filtering tool on a jointed-concrete pavement profile. ${ }^{(90)}$ The example showed plots of IMF combinations that helped distinguish slab curling from other content, such as texture and narrow dips at joints. Franta described a method for separating a profile into the following three components using the HHT: noise/surface texture, curl, and base trends. ${ }^{(91)}$ Each component included contributions from several IMFs produced by the transform. Franta provides an example of quantifying the curl of a slab in terms of temperature gradient in which the curl and base trend components are compared to slab deformation profiles predicted by ISLAB2005.

## Assessment

The literature reviewed in appendix A included the following findings pertinent to the research examined in the report:

- Curvature caused by curl and warp varies throughout the length of concrete slabs. Curvature at slab ends may disagree with simple slab models because of loss of contact with the subgrade, friction between adjacent slabs, and load-transfer devices.
- Variations in the curvature of measured slab profiles caused by sources other than curl and warp necessitate the use of smoothing, a curve fit, or some analysis technique that minimizes sensitivity to surface irregularities. Although curl and warp contributes to the
absolute curvature of slabs, the only justified assumption is that changes in curvature of a slab profile relate primarily to changes in curl and warp.
- Characterization of the status of a road segment by averaging the severity of curl and warp over many slabs reduces the influence of confounding variables. The distribution of values from individual slabs is also informative.
- Use of a single parameter to characterize curl and warp is advantageous if the use can be justified by a theoretical or experimental link to structural behavior. Measures that easily translate to an estimate of equivalent linear temperature gradient facilitate comparisons with past research and existing design practice.
- Under certain conditions, a statistical link exists between measures of curl and warp and measures of roughness, such as the IRI.
- Processing data for many slabs measured by an inertial profiler requires a reliable, preferably automated, method of detecting the location of joints.

## APPENDIX B. DESIGN FEATURES, MAINTENANCE HISTORY, AND PROFILE-MEASUREMENT HISTORY

## DESIGN FEATURES

## SPS-2 Sites

This section provides relevant information about SPS-2 sites provided in construction reports, a description of the LTPP SPS-2 core experiment, and a description of a proposed SPS-2 pavement-preservation experiment. (See references 7, 15, 19, and 92.)

Table 22 lists the variations in structural factors that appear at LTPP SPS-2 sites. These 24 combinations make up a factorial matrix with 2 values of slab thickness, 2 values of PCC flexural strength, 3 base designs, and 2 values of slab width. Each site includes 12 core sections. The sites in Kansas, North Carolina, Ohio, and Washington include sections 0201-0212, and the site in Arizona includes sections 0213-0224. The two groups have the same combinations of slab thickness, PCC flexural strength, and base design but have the opposite pairing of each combination with slab width.

The subgrade is silty sand with gravel at the Arizona site, silty clay at the Kansas site, primarily silty clay at the North Carolina site, silty clay at the Ohio site, and fine-grained sandy-silt material at the Washington site.

Table 23 lists the supplemental sections at each site and the structural factors known about each site. The Kansas, North Carolina, and Washington sites include control sections that were built using the State DOT's standard design. The control section in Kansas (200259) has a 6 -inchthick stabilized base above a 6-inch-thick modified fly ash subbase. The control section in North Carolina (370259) has a 4-inch PATB and includes a section (370260) that substitutes a 5 -inch-thick asphalt-treated base for the LCB on section 370207 for comparison. The control section in Washington (530259) has a 3-inch-thick asphalt-treated base over a 2 -inch-thick crushed surfacing base course.

The Arizona site includes four undoweled sections with skewed joints (040262-040265). Their doweled counterparts are $040213,040221,040223$, and 040215 , respectively. Three additional sections of doweled jointed plain concrete (040266-040268) were included with specialized designs of interest to the Arizona DOT. The Arizona site also includes two asphalt concrete (AC) sections (040260 and 040261).

The Ohio site includes seven supplemental sections with the same PCC thickness and various combinations of base designs and mix designs of interest to the Ohio DOT. Even-numbered sections were built using a higher-strength mix than odd-numbered sections.

## GPS-3 Sections

Table 24 provides information about the structural design of GPS-3 sections included in this study. The bound treated base for sections 063021 and 493011 were composed of a cement-aggregate mixture. All five sections had an untreated GB and an untreated subgrade. Table 25 provides more detail about the unbound base and subgrade of each section.

Table 24. GPS-3 section structural factors.

| Section | 28-Day Flexural <br> Strength (psi) | Layer 1 <br> Thickness <br> (Inches) | Layer 2 <br> Thickness <br> (Inches) | Layer 3 <br> Thickness <br> (Inches) | Layer 1 <br> Type | Layer 2 <br> Type | Layer 3 <br> Type |

| 273003 | Gravel | Sandy lean clay |
| 493011 | Crushed gravel | Clayey gravel with sand |

## CONSTRUCTION AND MAINTENANCE HISTORY

## SPS-2 Sections

Table 26 lists the date each site was opened to traffic and the source. These dates are used as a reference for determining a value of age in other parts of this report.

Table 26. SPS-2 site open to traffic dates.

| Site | Open to Traffic Date |
| :---: | :---: |
| Arizona | 01 -Oct-1993 |
| Kansas | 13-Jul-1992 $^{(15)}$ |
| North Carolina | 01 -Jul-1994 ${ }^{(18)}$ |
| Ohio | $01-$ Oct-1996 |
| Washington | 21 -Nov-1995 ${ }^{(16)}$ |

Some SPS-2 test sections were taken out of the LTPP study primarily because of rehabilitation to address pavement deterioration. The sections removed from the study and the date of removal include the following:

- 31-Dec-2003—sections 370201, 370202, 370205, 370206, 370209, and 370210.
- 16-Feb-2007-sections 390201, 390202, 390204, 390205, 390206, 390210, and 390259.
- 01-Sep-2012—sections 390209 and 390264.

All other test sections in North Carolina and Ohio and all test sections at the Arizona, Kansas, and Washington sites were included in the study over the entire interval.

Table 27 through table 30 list maintenance and rehabilitation performed on each test section that may affect the test section's measured roughness. Maintenance and rehabilitation were not performed at the Washington site.

Table 27. Maintenance and rehabilitation for Arizona SPS-2 sections.

| Section | Approximate Date | Description |
| :--- | :---: | :--- |
| 040213 | Aug-2009 | Partial-depth patching at joints and elsewhere |
| 040217 | Aug-2009 | Partial-depth patching at joints and elsewhere |

## GPS-3 Sections

Table 31 lists the section number, construction date, and the date each section was incorporated into the LTPP program for each GPS-3 section included in this study. The construction date for each section is used as a reference for determining a value of age in other parts of this report. Section 273003 was removed from the LTPP study on 01-Jul-2010. The other sections were still
active when this research was performed. The curl-and-warp analysis of section 183002, however, was terminated after July 2014 because it received an AC overlay.

| Section | Construction Date | Date Included in LTPP |
| :---: | :---: | :---: |
| 063021 | $01-A p r-1974$ | 28-Jan-1988 |
| 133019 | 01-Dec-1981 | 01-Jan-1987 |
| 183002 | 01-Aug-1976 | 01-Jan-1987 |
| 273003 | 01-Oct-1985 | 01-Jan-1987 |
| 493011 | 01-May-1986 | 05-Apr-1989 |

Table 32 lists major maintenance and rehabilitation performed on each section.
Table 31. Dates of construction and incorporation into LTPP for GPS-3 sections.

## PROFILE-MONITORING HISTORY

## SPS-2 Sections

Table 33 through
table 37 list the visit number, measurement date, ranges of time, number of repeat measurements, and section details for each profile-measurement visit to the SPS-2 site. Visit numbers are assigned to each sequence of visits for reference in other parts of this report. In some cases (e.g., visit 02 to the Arizona site), the tables list only a single value for time because the same measurement time was recorded for the entire set of repeat measurements.

In many cases, all test sections were included in a single set of passes over the site (e.g., visits 01 through 11 to the Arizona site). In other cases, portions of a site, including one or more test sections, were measured in separate sets of passes (e.g., visits 12 through 22 to the Arizona site). These cases are listed separately in Table 33 through

Table 37 because the timing of the measurements is different. Some sections do not appear in later visits because they had been taken out of the LTPP study.

Table 33. Profile-measurement history for Arizona SPS-2 site.

| Visit | Date | Time | Repeats | Sections |
| :---: | :---: | :---: | :---: | :---: |

Table 38 through table 40 list the visit number of the seasonal measurement program, measurement date, ranges of time, and number of repeat measurements for SMP sections $040215,370201,370205,370208,370212$, and 390204. Table 39 lists measurements of sections 370209,370210 , and 370259 . These measurements were not SMP sections, but sections 370209, 370210 , and 370259 were contained within the range of raw profile measurements that were collected during some visits to SMP sections. A second set of profile measurements was collected on section 040267 in the midafternoon following visit 12 to the Arizona SPS-2 site. These measurements were included in the analysis as visit S01 to section 040267.

Table 38. Profile-measurement history for SMP section 390204.

| Visit | Date | Time | Repeats |
| :---: | :---: | :---: | :---: |
| S01 | 15-Aug-1996 | $13: 15$ | 7 |

## GPS-3 Sections

Table 41 through table 45 list the visit numbers, measurement dates, ranges of time, and number of repeat measurements for each profile-measurement visit for each GPS-3 section. Visit numbers are assigned to each sequence of visits for reference in other parts of this report. In some cases (e.g., visit 01 to section 063021 ), the tables list only a single value for time because
the profile data headers recorded the same measurement time for the entire set of repeat measurements.

Table 41. Profile-measurement history for GPS section 063021.

| Visit | Date | Time | Repeats |
| :---: | :---: | :---: | :---: |
| 01 | 01-Feb-1990 | $17: 20$ | 5 |
| 02 | 20-Sep-1990 | $11: 09-11: 58$ | 7 |

## APPENDIX C. DATA-QUALITY SCREENING

Researchers performed a screening process to select five repeat profile measurements from each visit to each section. The five measurements among the group of up to nine available passes within a visit were selected that exhibited best agreement with each other. Agreement between any pair of profile measurements was judged by cross-correlating the measurements after applying the IRI filter. The details of this method are described in Karamihas. ${ }^{(93)}$ Researchers applied the IRI filter to the profiles before cross correlating them.

High cross correlation between the IRI-filtered profiles requires that their overall roughness is in agreement, as well as the details of the profile shape that affect the IRI, including the severity and distribution of roughness within the section. When 9 repeat profile measurements (i.e., passes) were available, cross-correlating all possible profile pairs produced a total of 36 correlation values for left-side profiles and 36 correlation values for the right. Researchers summarized the composite correlation level for a given set of 5 profiles using an average of the 20 appropriate cross correlation values. The subgroup that produced the highest composite correlation was selected; the other repeat profile measurements were excluded from the analyses discussed in this report. In a few cases, the cross correlation was based on left-side profiles because only left-side profiles were available.

Table 46 lists the results for each visit of each section. The table provides the time and date of the first selected pass, number of available passes, selected pass numbers, and their composite correlation. For visits with five or fewer available passes, all passes were included. Visits 19 through 21 to the SPS-2 site in Arizona included three passes; seasonal visit S01 to section 370201 included four passes; visit 29 to the SPS-2 site in North Carolina included four passes. Pass four over the North Carolina SPS-2 site in visit 26 did not include profiles for the right side.

Overall, 9,570 passes in 1,941 sets of up to 5 repeats comprise the dataset listed in this appendix.
Table 46. Selected repeats.

| Section | Visit | Date | Time | Available <br> Repeats | Selected <br> Repeats | Composite <br> Correlation |

## APPENDIX D. ROUGHNESS VALUES

This appendix lists the left IRI, right IRI, MRI, and HRI values for each visit of each section. In most cases, the roughness values are the average for five repeat runs. The five runs were selected from a group of as many as nine runs by automated comparison of profiles as described in appendix C. SD values are also provided for left and right IRI to reveal cases of high variability among the five measurements. However, the screening procedure used to select five runs usually helped reduce the level of scatter.

The discussion of roughness in the main report emphasizes the left and right IRI. Nevertheless, other indices provide useful additional information. MRI is the average of the left and right IRI value. HRI is calculated by converting the IRI filter into a half-car model. ${ }^{(94)}$ The conversion is accomplished by collapsing the left and right profile into a single profile in which each point is the average of the corresponding left and right elevation. The IRI filter is then applied to the resulting signal. The HRI is similar to the IRI except that side-to-side deviations in profile are eliminated. The result is that the HRI value for a pair of profiles will always be lower than the corresponding MRI value. Comparing the HRI and MRI values provide a crude indication of the significance of roll (i.e., side-by-side variation in profiles) to the overall roughness. When HRI is low compared to MRI, roll is significant. This is common among asphalt pavements. ${ }^{(95)}$ Certain types of pavement distress, such as longitudinal cracking, may also cause significant differences between HRI and MRI.

Figure 81 compares the HRI to MRI for profile measurements of PCC sections. The comparison includes 9,359 pairs of roughness values and excludes AC sections 040260 and 040261 . The figure shows a best-fit line with a zero intercept and a line of equality. The slope of the line is 0.910, which produced a root mean square (RMS) residual of 3.41 inches $/ \mathrm{mi}$. A typical range for concrete pavement is 0.90 through 0.95 . Note that a better linear fit was found without forcing a zero intercept. A simple linear fit produced a slope of 0.958 and an intercept of -5.03 inches $/ \mathrm{mi}$. This line had an RMS residual of 3.18 inches $/ \mathrm{mi}$.

Table 47 provides roughness values and lists the date of each measurement and age of each section. On the SPS-2 sections, the age is the time elapsed since the project was opened to traffic. On the GPS-3 sections, the age is the time elapsed since the construction date. Figure 82 through figure 166 show left and right IRI versus age for the 85 test sections and use equivalent scaling for the roughness axis. Figures for sections from the same SPS-2 project use the same age scale. The figures show annotations along the age axis for maintenance and rehabilitation.

## APPENDIX E. IDENTIFYING JOINT LOCATIONS

This appendix describes the algorithm used to identify joint locations within measured profiles for slab-by-slab quantification of curl and warp.

## BACKGROUND

Multiple algorithms have been proposed for joint identification in support of profile-based measurement of faulting for pavement management. ${ }^{(96,97)}$ These algorithms search for step changes in elevation at potential faults, local minima within the profile with an adaptive threshold adjusted to seek the expected number of joints, or narrow dips that appear with an expected spacing within the profile processed with a high-pass filter. ${ }^{(98-100)}$ Algorithms applied to quantify curl and warp search for joints at locations where curvature exceeds a given threshold or for narrow dips within the profile processed with a high-pass filter. ${ }^{(3,75)}$

Each algorithm is suited to specific expectations regarding the content within the profile. The most effective choice depends on aspects of pavement condition, such as the relative levels of faulting, slab curl, and joint distress within the profile; properties of the pavement surface that affect short-wavelength profile content, such as surface texture depth and type, joint width, and the status of joint sealant; and details of the measurement process, including the profiler heightsensor footprint, low-pass filtering, and recording interval.

The algorithm applied in this research was developed specifically for use on profile data collected for the LTPP program. The profiles were measured with well-documented field procedures and provisions for quality control. ${ }^{(8)}$ Further, the success rate of the algorithm was improved by synchronizing the profiles for consistent longitudinal alignment throughout the monitoring history of each section and analyzing the profiles in groups.

The algorithm is based on a spike-detection procedure proposed by Chang et al. and most closely resembles an algorithm described by Karamihas and Senn. ${ }^{(2,6)}$ The joint-finding strategy included the following:

- Identification of potential joint locations by seeking narrow downward spikes in each profile.
- Prioritization of locations where the spikes appeared consistently in both the left- and right-side profiles with provisions for skewed joints.
- Prioritization of locations where the spikes appeared consistently in repeated profile measurements from a given monitoring visit and among several consecutive visits.
- Recognition of locations with detected spikes that appeared throughout a test section with the expected joint spacing or joint-spacing pattern.

## ANALYSIS STEPS

## Step 1: Select a Group of Profiles

The joint-finding procedure was applied to several profiles simultaneously as a group. All profiles in the group covered the same test section and had consistent longitudinal alignment.

With few exceptions, profiles were grouped over all measurement visits made by the same profiler type to a specific test section. Profiles measured by different profiler types were not mixed in case different analysis settings were needed for each profiler type.

For example, the procedure was applied to a group of 60 profile measurements of section 390203 collected from 27-Dec-1996 through 04-Nov-2001. The 60 profile measurements include 5 repeat passes per visit over 6 visits and left and right profiles from each pass. The profiles were grouped together because the same profiler measured them. Likewise, a second group included 100 profiles collected from 06-Dec-2002 through 22-May-2012 by another profiler, and a third group included 40 profiles collected starting 03-Jul-2014 by another profiler.

Profiles collected for the SMP were also grouped by profiler type but were not incorporated into groups from regular monitoring visits from the same era. For example, 60 profiles measured during 6 regular visits to section 390204 by a specific profiler were analyzed as a group and 140 additional profiles from seasonal measurements by the same profiler were analyzed as a separate group. In part, the use of unique groups for seasonal visits was a matter of convenience when applying the calculation routines written for the analysis. The groups were separated because profiles from regular visits covered a range outside of the boundaries of the test section (i.e., the analysis incorporated joints just outside the test section boundaries to help establish the expected spacing pattern). Profiles from seasonal visits typically did not include pavement outside the test-section boundaries.

## Step 2: Filter the Profiles

High-pass filter each profile with an antismoothing moving average filter using a base length of 0.82 ft .

## Step 3: Normalize the Profiles

Normalize each filtered profile by its SD.

## Step 4: Seek the Negative Spikes

Search each normalized trace and list the longitudinal position and the magnitude of any negative spike with a value below a given threshold. A default threshold value of -3 was used for most profile groups. Figure 167 shows a profile measured on section 390203 after high-pass filtering and normalization. The threshold value for negative spikes of -3 is marked on the graph.

Source: FHWA.
Figure 167. Graph. Profile measured on section 390203 after high-pass filtering and normalization.

Lower threshold values were used for some groups of profiles. For example, the value was reduced to -2.5 for profiles from the SPS-2 site in Washington because the site included coarse surface texture and the downward spikes at the joints had lower magnitude relative to the content away from the joints. A lower threshold value was also used on profiles from sections 040222, $063021,183002,200210,200259,273003,370203,370205$, and 390204. For these sections, some combination of coarse surface texture, narrow gaps at the joints, and higher joint sealant necessitated the reduction in the spike-detection threshold. In some cases, the threshold was reduced for groups of profiles collected after January 2013 because low-pass filtering reduced the magnitude of the spikes at joints.

## Step 5: Remove Lesser Spikes

Eliminate any spike within a given range of a deeper spike. The default range value, which was used for most sets of profiles, was 0.2 ft . In some cases where cracking or other distress appeared near joints, other values as low as 0.1 ft and as high as 0.8 ft were used.

## Step 6: Aggregate Across the Profile Group

Assemble into a single list the qualifying spike locations for the left and right profiles of all profile measurements within the group. For sections with skewed joints, offset values of longitudinal position for left-side profiles by 0.919 ft . Sections 040262-040265, 063021, and 493011 included skewed joints.

## Step 7: Sort the List

Sort the list of qualifying spike locations in ascending order of longitudinal position.

## Step 8: Consolidate Nearby Spikes into Clusters

Consolidate any set of closely spaced spike positions into a cluster. Merge spike positions for which no gap larger than a preset value (i.e., a gap limit) exists between consecutive values.

Set a limit for the total range covered by a single cluster of spikes (i.e., a cluster range limit). For each cluster of spikes, record the range of longitudinal position values, average longitudinal position value, and number of spikes included in the cluster. To do this, apply the following steps:

- Step 8a: Open a new spike cluster using the first item in the list.
- Step 8b: If the list of spikes is complete, close the final cluster and terminate the consolidation procedure. If not complete, promote the next item on the list to the current item.
- Step 8c: If the distance from the previous item to the current item is no greater than the gap limit and the distance from the first item in the spike cluster to the current item is no greater than the cluster range limit, add the current item to the open spike cluster and return to step 8 .
- Step 8d: If the distance from the previous item to the current item is greater than the gap limit or the distance from the first item in the spike cluster to the current item is greater than the cluster range limit, close the current spike cluster and open a new spike cluster with the current item as the first member. Return to step 8 b .

The default value for gap limit was 0.1 ft ; however, values as high as 0.4 ft were used and a value of 0.2 ft was used in approximately one-third of the cases. A cluster range limit of 0.82 ft was used in nearly every case.

For each group of profiles, this procedure produced a list of spike clusters that outnumbered the joints within a test section, often by a wide margin. However, spike clusters with counts approaching or equal to the number of profiles in the set typically only appeared at joints or transverse cracks.

Table 48 lists the most well-populated spike clusters from a group of 60 profile measurements of section 390203 collected from 27-Dec-1996 through 04-Nov-2001. Analysis of this profile group produced 2,291 spikes in 167 clusters, which included 96 clusters with only 1 spike, 15 clusters with 2 spikes, and 7 clusters with 3 spikes. The clusters with only three spikes are not shown in Table 48.

Table 48. Spike clusters from six visits to section 390203.

| Start of Range <br> (ft) | End of Range <br> (ft) | Average Position <br> (ft) | Number of Spikes | Joint-Spacing Compatibility Score |

## Step 9: Evaluate Each Spike Cluster in the List

Calculate a joint-spacing compatibility score for each spike cluster. To do this, seek other clusters that appear at the expected distances from the cluster under evaluation within an acceptable tolerance.

The compatibility score for a spike cluster is the sum of the spike counts from every cluster that appears at an expected distance within a given tolerance. For an expected joint spacing of 15 ft , any spike cluster that appears a multiple of 15 ft from a spike cluster contributes to the compatibility score. The distance must be within a preset tolerance, which is expressed as a percentage of the nominal joint spacing.

The distance tolerance for compatibility was set at a default value of 3 percent of the expected joint spacing, which corresponds to a tolerance of 0.45 ft for $15-\mathrm{ft}$-long slabs. A value of 6 percent was used on test sections where the joint spacing varied somewhat relative to the nominal value. In some cases, the tolerance was set as high as 12 percent. This tolerance was needed on test sections where the joint-spacing pattern did not adhere to the nominal value throughout the entire section.

For test sections with multiple slab lengths, the joint-spacing compatibility score was evaluated multiple times. Some test sections had a nominal joint-spacing pattern that repeated every fourth slab. On those sections, the compatibility score at each spike cluster was evaluated once for each possible position of a potential joint within the four-slab pattern and the highest score was reported. For multiple-slab patterns, the distance-tolerance threshold was interpreted as a percentage of the average slab length within the pattern.

Compatibility scores were typically only calculated for clusters with a spike count above a given threshold, expressed as a percentage of the number of profiles in the group. The default value was 30 percent, which was used on the majority of profile groups. For example, the group examined in Table 48 included 60 profiles and compatibility scores were only calculated for clusters that included 18 spikes or more.

In a few instances, iteration was required to determine the spike-count threshold that yielded a complete set of joint locations. For example, lower values were used in cases where downward spikes did not appear reliably at every joint in every profile measurement. In rare cases, every spike group was evaluated for compatibility.

## Step 10: Designate the Most Compatible Spike Cluster as the Principal Joint

Designate the spike cluster with the highest compatibility score as a joint. If multiple clusters share the highest compatibility score, select the joint farthest upstream.

In Table 48, the highest compatibility score of 1,836 occurs at the spike cluster with an average position of 431.68 ft . Although this score is the highest, it is lower than the maximum possible score. If the spike cluster at each joint included 60 spikes, which is one per pass, then compatibility with the 35 joints within the range covered by the analysis would have produced the maximum possible score of 2,100 .

## Step 11: Seek Other Joints Downstream

Seek the adjacent joint location in the forward direction from the principal joint. Select the spike cluster with the highest compatibility score within the expected distance window. The distance window extends from the shortest expected joint spacing to the longest expected joint spacing in the designated pattern with an additional margin added at both ends. The margin is determined by a joint window tolerance, which is expressed as a percentage of the joint spacing. Each time a joint is found, seek the following joint using the same procedure until the end of the profile group range is reached.

The default value of joint window tolerance was 3 percent. This corresponds to a joint window of 14.55 to 15.45 ft for test sections with a constant nominal joint spacing of 15 ft . A section with a joint-spacing pattern of $13,12,18$, and 19 ft corresponds to a joint-spacing window of 11.64 to 19.57 ft .

The default value for joint window tolerance was applied to a majority of the profile groups. A range of values from 1.5 to 15 percent was used on various test sections depending on how consistently the actual joint spacing adhered to the nominal pattern.

## Step 12: Seek Other Joints Upstream

Repeat the process from step 11, starting from the principal joint and extending in the reverse direction until the end of the section is reached.

## DISCUSSION

## Joint Position and Joint Window

Table 49 shows the outcome of the joint-finding procedure for the profile group in Table 48. The position of each joint listed in Table 49 is the average position of the spikes in the joint cluster. Table 49 also lists the distance between adjacent joint positions. In subsequent analysis of curl and warp of each slab, such as the calculation of radius of relative stiffness, the distance between joints is used as the slab length.

Table 49 also lists the spike cluster range, which is the total distance between the first and last spike in the source cluster. The spike cluster range provides a measure of the potential variation in joint locations within the profile group. Subsequent analysis of curl and warp includes a curve fit on the profile within each slab. This analysis excludes the spike cluster range to ensure that downward spikes in profile do not affect the curve fit. The curve fit is performed on an area within the profile that extends from the end of the spike cluster range from the leading joint to the start of the spike cluster range for the trailing joint. For example, the second and third joints in Table 49 define a 15.02 -ft-long slab running from 11.32 to 26.34 ft from the section start. However, as shown in Table 48, the curl-and-warp analysis will consider a 14.83-ft-long area running from 11.42 ft to 26.25 ft from the start of the section.

The average spike cluster range for joints located in profiles measured by LTPP was 0.24 ft ; 95 percent of the joints had a range of 0.44 ft or less.

Table 49. Joint locations from six visits to section 390203.

## Termination

In some cases, the joint-finding analysis was terminated prior to the end of the monitoring period because of the following changes in the structural state of test sections:

- Analysis of section 200205 was terminated after 21-Sep-2012 because wide patches were installed at many joints.
- Analysis of section 200210 was terminated after 21-Sep-2012 because the section was diamond ground.
- Analysis of section 390208 and section 390212 was terminated after 22-May-2012 because slab replacement and patching altered some of the slabs.
- Analysis of section 183002 was terminated after 26-Apr-2011 because the section received an overlay.
- Analysis of section 493011 was terminated after 26-Oct-2010 because joint restoration included the installation of wide patches at many joints.

## Extrapolation

The algorithm succeeded in locating all joints for profiles collected from December 1996 through January 2013 because those profiles were measured using narrow-footprint height sensors. Profile data collected before December 1996 were measured using a height sensor with a footprint that was 6 inches wide and 0.24 inches long and was less likely than profilers used in subsequent years to register a downward spike in a reading at a joint. ${ }^{(14)}$ Profiles were collected using a sampling interval of 2 inches, smoothed using a moving average over a base length of 12 inches, and recorded at an interval of 6 inches. Downward spikes in elevation did not routinely appear at joints in these profiles. For profiles measured in this era, joint locations were detected from later measurements by a different profiler.

After January 2013, profile data were recorded after the application of low-pass filtering. Downward spikes at the joints did not stand out relative to other content within profile data from the Washington SPS-2 site because those test sections included coarse surface texture. Joint locations for profiles collected after January 2013 at the Washington site were assumed to be the same as in the visit in May 2012.

## Joint Spacing

The joint spacing for every section included some variation around the nominal spacing pattern and some test sections included one or more joints that did not adhere to the pattern at all. Any exception to the expected joint-spacing pattern greater than 0.5 ft was verified by comparing the exception to transverse joint distance values recorded in LTPP manual distress surveys of faulting.

An additional rule for identifying joints was applied for some test sections with high levels of variation around the nominal spacing pattern. The additional rule qualifies any location as a joint if enough spikes are detected. This rule is applied in steps 11 and 12 previously noted. The criterion designates a spike cluster as a joint that includes a sufficient number of spikes as a percentage of the number of profiles in the group, regardless of whether the location is within the joint-window tolerance. The test sections using the additional rule are sections 370201-370203, 370207-370212, 370259, 200259, 200202, 063021, 390264, and 493011.

Table 50 provides details about the joint spacing within each section.

Table 50. Joint-spacing details.

| Section(s) | Nominal Pattern (ft) | Notes |
| :---: | :---: | :--- |
| $040213-040224$ | 15 | No notes. |
| $040262-040265$ | $15-12-14-13$ | Skewed joints. |
| $040266-040268$ | $15-13-14-17$ | No notes. |
| 063021 | $12-13-19-18$ | Skewed joints. <br> One 29-ft slab. |
| 133019 | 20 | No notes. |
| 183002 | $13-12-18-19$ | Skewed joints. |
| $200201-200212$ | 15 | High variation in spacing. |
| 200210 | 15 | One 16.8-ft-long slab. |
| 200212 | 15 | One slab group 11.9-13.4-19.4 ft. |
| 200259 | 15 | One slab group 11.5-17.9 ft. |
| 273003 | $13.0-15.5-13.9-16.8$ | Variation from this pattern of up to 0.85 ft. |
| $370201-370212$ | 15 | High variation in spacing. |
| 370201 | 15 | First full slab 13.6-ft long. |
| 370211 | 15 | One slab group 17.1-2.8 ft. |
| 370259 | $21.6-19.2-18.7-20.6$ | Variation from this pattern of up to 0.58 ft. <br> The 21.6-ft-long slab was missing in one instance of the <br> pattern. |
| 370260 |  | No notes. |
| $390201-390212$ | 15 | No notes. |
| $390259-390265$ | 15 | No notes. |
| 390264 | 15 | One slab group 10.6-6.0-13.6 ft. <br> One slab group 10.5-6.0-13.5 ft. |
| 493011 | 15 | Skew <br> A wide transverse crack disrupts the pattern near the <br> center of the section. <br> Variation from this pattern of up to 0.5 ft. |
| $530201-530212$ | $17-18-13-12$ | High variation in spacing. |
| 530259 | $14.1-13.1-8.8-9.9$ | Variation from this pattern of up to 0.7 ft. |
|  | 15 |  |

Section 063021 included a $29-\mathrm{ft} \mathrm{slab}$ near the center of the section in place of an $18-\mathrm{ft} \mathrm{slab}$ and $12-\mathrm{ft}$ slab within the pattern. A transverse crack appeared within the slab. Atypical settings for the joint-finding algorithm were required to accommodate the crack. Three sections at the Kansas SPS-2 site and two sections at the North Carolina SPS-2 site included a slab or a group of consecutive slabs that differed in length from the nominal spacing of 15 ft , as described in Table 50. At two locations within section 390264 , a $6-\mathrm{ft}$ patch was installed over an existing joint that disrupted the nominal joint-spacing pattern.

Joint-spacing values at the Kansas and North Carolina sites varied from the nominal value to greater extent than the Arizona, Ohio, and Washington sites. Excluding the special cases listed in Table 50, the core test sections at the Kansas site included 380 slabs that were fully within test-section boundaries. Joint-spacing values for these slabs ranged from 14.40 to 15.70 ft , with an average value of 15.00 ft and an SD of 0.21 ft . Excluding the special cases listed in Table 50, the core test sections at the North Carolina site included 384 slabs that were fully within testsection boundaries. Joint-spacing values for these slabs ranged from 14.11 to 15.94 ft , with an average value of 14.99 ft and an SD of 0.24 ft . In contrast, 385 slabs within the core sections at the Arizona site had joint-spacing values that ranged from 14.74 to 15.39 ft , with an average value of 15.00 ft and an SD of 0.06 ft . Joint-spacing values for the core sections at the Ohio and

Washington sites had variation comparable to the Arizona site, with SD values of 0.10 and 0.09 ft , respectively.

On section 273003, the nominal spacing pattern was established after inspecting the measured profiles. The values listed in Table 50 are the average joint-spacing values for each member of the pattern within the section. However, individual joint-spacing values varied from the nominal values by up to 0.85 ft .

On section 370259 , the joint-finding algorithm used a constant nominal joint spacing of 20 ft with a high tolerance. The results revealed a four-slab pattern with average nominal values of 21.6, 19.2, 18.7, and 20.6 ft . However, the first slab was missing in one instance of the pattern and variation from the average values of up to 0.55 ft was observed.

On section 493011, the joint-finding algorithm used a constant nominal joint-spacing pattern of $13,12,17$, and 18 ft . The results revealed a four-slab pattern with average nominal values of $12.8,12.2,16.9$, and 17.9 ft . The pattern is disrupted over a 58 - ft -long area near the center of the section, which included a wide transverse crack. Taking the crack into consideration, this area includes four slabs of various lengths that do not adhere to the nominal pattern. Atypical settings for the joint-finding algorithm were required to accommodate the pattern disruption.

On section 530259, the nominal spacing pattern was established after inspecting the measured profiles. The values listed in Table 50 are the average joint-spacing values for each member of the pattern within the section. However, individual joint-spacing values varied from the nominal values by up to 0.7 ft .

## FHWA CURL-AND-WARP STUDY PROFILES

The joint-finding algorithm in this appendix was also applied to diurnal and seasonal profile measurements from the FHWA curl-and-warp study, Impact of Temperature Curling and Moisture Warping on Jointed Concrete Pavement Performance. ${ }^{(6)}$ For this dataset, all profiles from a given section were analyzed as a single group. The group typically consists of 160 profiles for sections with seasonal and diurnal measurements, which includes 4 seasons, 4 times per day per season, 5 passes per time of day, and profiles from 2 sides in every pass. Sections with diurnal measurement only include 40 profiles. These profiles were measured with a high-speed profiler that used a point laser with a narrow footprint as a height sensor. The profiler was modified to provide profile at a sample interval of 0.25 inches to facilitate the jointfinding process. ${ }^{(85)}$

The joint-finding algorithm was applied to profiles with default values similar to those used on LTPP profile measurements. In several cases, a larger threshold value for spike magnitude $(-4$ or -5$)$ was applied because the negative spikes at joints were deeper.

## APPENDIX F. ESTIMATION OF SLAB CURL

The levels of curl and warp present within each profile were estimated using slab-by-slab analysis of local profile segments. Measured profiles of individual slabs were isolated using the joint-finding procedure described in appendix E. Deformation within each slab profile due to curl and warp was estimated using a curve fit to the Westergaard equation. The Westergaard equation predicts the deformation of a concrete slab in response to a linear strain gradient throughout its depth.

## WESTERGAARD DEFORMATION MODEL

The curve-fitting procedure for measured slab profiles used an idealized shape proposed by Westergaard. ${ }^{(20)}$ The idealized profile is based on the assumption of a linear strain gradient through the depth of the slab, unrestrained slab ends, and an infinite slab along the undeformed axis. Westergaard provided the solution for an infinitely long pavement of finite width. Vertical deformation $(z)$ depends on distance from the slab center $(x)$ as shown in the equations in figure 168.

$$
z=-z_{0} \frac{2 \cos \lambda \cosh \lambda}{\sin 2 \lambda-\sinh 2 \lambda}\left[(-\tan \lambda+\tanh \lambda) \cos \frac{x}{l \sqrt{2}} \cosh \frac{x}{l \sqrt{2}}+(\tan \lambda+\tanh \lambda) \sin \frac{x}{l \sqrt{2}} \sinh \frac{x}{l \sqrt{2}}\right]
$$

A. Equation. $z$.

$$
\begin{aligned}
& z_{0}=\frac{-(1+\mu)\left(\alpha \Delta T+\Delta \varepsilon_{s h}\right)}{h} l^{2} \\
& \Delta \varepsilon_{s h} / h=\text { moisture gradient. } \\
& \alpha \Delta T / h=\text { temperature gradient. }
\end{aligned}
$$

B. Equation. $z_{r}$.

$$
\begin{aligned}
& \lambda=\frac{b}{l \sqrt{8}} \\
& b=\text { slab width. }
\end{aligned}
$$

C. Equation. $\lambda$.

$$
l=\sqrt[4]{\frac{E h^{3}}{12\left(1-\mu^{2}\right) k}}
$$

D. Equation. $l$.

Figure 168. Equation. Relationship of slab elevation to position.
This study applies the solution to predict vertical deformation as a function of longitudinal distance from the center of the slab. As such, $b$ represents slab length in this report, rather than slab width.

The curve-fitting procedure accepts $b, E, \mu$, and $k$ as inputs to the model and estimates the linear strain gradient by fitting the idealized slab profile to a measured profile. The estimate of linear strain gradient required to deform the slab into the measured shape is the PSG, which relates to figure 168 and is shown in Figure 169.

$$
P S G=\frac{\left(\alpha \Delta T+\Delta \varepsilon_{s h}\right)}{h}
$$

Figure 169. Equation. PSG.

## SLAB PROPERTIES

Local slab profiles were extracted from sectionwide measured profiles using the locations of the surrounding joints, as described in appendix E. The length associated with each slab profile was the distance between joint locations.

Material properties were assumed to be constant for all slabs within a given test section and throughout the monitoring history of each section. A constant value of 0.15 was used for Poisson's ratio for all test sections in this study. LTPP database table L05B provided slab thickness values, which were based on cores that were collected at the ends of each section. ${ }^{(8)}$ Table 51 and Table 52 list the values of slab thickness for each test section.

Elastic modulus and modulus of subgrade reaction were derived from FWD testing using two methods of analysis: AREA and Best Fit. Khazanovich, Tayabji, and Darter describe the methods as follows:

The Best Fit method solves for a combination of the radius of relative stiffness, $l$, and the coefficient of subgrade reaction, k , that produces the best possible agreement between the predicted and measured deflections at each sensor. The AREA method ... estimates the radius of relative stiffness as a function of the AREA of the deflection basin. ${ }^{(101)}$

The Best Fit method uses least squares minimization between measured and predicted deflection, with relative weighting factors assigned to the output of each deflection sensor. ${ }^{(102)}$

Smith et al. and Hall and Mohseni describe the AREA method as it is applied to the sensor configuration used in the LTPP program. ${ }^{(102,103)}$ The AREA parameter characterizes the measured deflection basin in units of distance (i.e., length). AREA is a sum that includes one term per deflection sensor. Each term is the product of the deflection measurement at a given location and the distance to an adjacent sensor. The sum approximates rectangular integration of the deflection basin in two dimensions, with an additional term for the outermost deflection measurement. The sum is normalized by the deflection measured directly under the load plate. Radius of relative stiffness is computed directly from the AREA parameter using an empirical relationship established for the specific sensor placement and loading conditions. In turn, a theoretical relationship by Westergaard provides the modulus of subgrade support, given the applied load, the load radius, the maximum deflection under the load, and the radius of relative stiffness. ${ }^{(20)}$

In both methods, elastic modulus is calculated from the derived values of radius of relative stiffness and modulus of subgrade reaction. Table 51 and Table 52 list elastic modulus, modulus of subgrade support, and radius of relative stiffness produced by the AREA and Best Fit methods, respectively.

Table 51. Test-section properties using AREA method.

## SLAB-BY-SLAB ANALYSIS

Karamihas and Senn describe the method of estimating PSG for each slab profile. The analysis steps are summarized in this section. ${ }^{(2)}$

## Step 1: Crop the Profile

Crop the profile of the slab to exclude the negative spikes at the joints, the small area near the joint where downward spikes were detected during the joint-finding procedure described in appendix E. The start-of-range and end-of-range values shown in Table 48 define the excluded areas. For example, the first two joints in section 390203 appear at 11.32 and 26.34 ft . To avoid the possibility of including a downward spike in curve fit, the slab profile is cropped to run from 11.42 through 26.25 ft .

## Step 2: Shift

Move the origin of the horizontal scale to the longitudinal slab center.

## Step 3: Detrend

Detrend the measured slab profile. Apply a least-squares linear fit to the profile segment and subtract the best-fit line.

## Step 4: Curve Fit

Perform a nonlinear curve fit of the Westergaard model to the measured slab profile. In this study, curve fitting was performed using functions MRQMIN and MRQCOF provided in

Numerical Recipes. ${ }^{(104)}$ These routines perform a nonlinear least-squares curve fit using the Levenberg-Marquardt algorithm. PSG, as defined in Figure 169, is the only fitted parameter.

## APPENDIX G. PSG VERSUS TIME USING THE BEST FIT METHOD

This appendix provides plots of PSG versus age for the 83 jointed PCC test sections included in this study (figure 170 through figure 252). PSG values were derived using radius of relative stiffness values produced by the Best Fit method. PSG values are expressed in units of microstrain per inch ( $\mu \varepsilon / \mathrm{inch})$. PSG values for each visit are a weighted average of all slab-byslab values from repeat passes selected for that monitoring visit. The average typically included five repeat passes. A weighting is assigned to each PSG value in proportion to the corresponding slab length. For slabs that straddle test-section boundaries, a weighting is assigned to the PSG value in proportion to the length within the test section.

On the SPS-2 sections, the age is the time elapsed since the project was opened to traffic. On the GPS-3 sections, the age is the time elapsed since the construction date. Figures for sections from the same SPS-2 project use the same age scale.

## APPENDIX H. PSG VERSUS TIME USING AREA METHOD

This appendix provides plots of PSG versus age for the 83 jointed PCC test sections included in this study (figure 253 to Figure 335). PSG values were derived using radius of relative stiffness values produced by the AREA method. PSG values are expressed in units of microstrain per inch ( $\mu \varepsilon / \mathrm{inch})$. PSG values for each visit are a weighted average of all slab-by-slab values from (typically five) repeat passes selected for that monitoring visit. A weighting is assigned to each PSG value in proportion to the corresponding slab length. For slabs that straddle test sections boundaries, a weighting is assigned to the PSG value in proportion to the length that is within the test section.

On the SPS-2 sections, the age is the time elapsed since the project was opened to traffic. On the GPS-3 sections, the age is the time elapsed since the construction date. Figures for sections from the same SPS-2 project use the same age scale.

## APPENDIX I. LINEAR REGRESSION STATISTICAL OUTPUTS

## PSG LINEAR REGRESSION

Table 53 shows the results of the linear regression analysis performed on PSG values calculated using Best Fit and AREA methods. The results show the PSG intercept $\left(P S G_{i}\right)$, the initial PSG after the pavement was constructed, the PSG slope $\left(P S G_{s}\right)$, and the change in PSG per year after construction up to 10 years. The $P S G_{i}$ and $P S G_{s}$ values are used for analysis in chapter 8 and chapter 9.

Table 53. Linear regression slope and intercept for PSG (first 10 years).

## CLIMATE FACTORS

Table 54 shows the average temperature and humidity for the first month after construction. It also shows the average daily difference between maximum and minimum values of temperature and humidity of the first month after construction. These averages are based on hourly temperature and humidity from the MERRA climate database.

Table 54. MERRA climate database-first-month averages. ${ }^{(21)}$

|  | Average <br> Temperature <br> $\left({ }^{\circ} \mathbf{F}\right)$ | Average Humidity <br> $(\%)$ | Average Daily <br> Temperature <br> Maximum <br> Difference ( $\left.{ }^{\circ} \mathbf{F}\right)$ | Average Daily <br> Humidity <br> Maximum <br> Difference (\%) |
| :---: | :---: | :---: | :---: | :---: |
| State Code | 72.8 | 33.3 | 25.5 | 31.6 |

| 37 | 59.4 | 87.9 | 44.6 | 81.5 |
| 39 | 51.1 | 85.8 | 39.6 | 651.5 |
| 53 | 49.3 | 77.3 | 10.9 | 406.4 |

${ }^{1}$ Cumulative degrees of days below freezing $\left(32^{\circ} \mathrm{F}\right)$.

## STRUCTURAL FACTORS

Table 57 shows structural properties (other than layer thickness) of the PCC slab, including average slab width, slab length, paste volume, modulus of rupture, elastic modulus, and temperature gradient. The temperature gradient is based on measurements taken during FWD testing at incremental depths from the pavement surface. The paste volume is percent of the PCC mix that is paste (i.e., water, cement, and fly ash).

Table 57. Test section structural design factors.

| State Code | SHRP ID | Average Slab Width (ft) | Average Slab Length (ft) | $\begin{array}{\|c} \text { Average } \\ \text { Paste } \\ \text { Volume (\%) } \\ \hline \end{array}$ | Average PCC <br> Modulus of Rupture (psi) | Average PCC Elastic Modulus (psi) | Average <br> Temperature Gradient <br> During FWD Testing ( ${ }^{\circ}$ F /Inch) |

SHRP = Strategic Highway Research Program.
Table 58 shows the thickness of each layer in the test section by layer type. All test sections have been categorized into GB, PATB, and LCB. In the case of sections with a GB under a treated base (i.e., PATB and LCB), the GB is considered a granular subbase. Soil layers that have been chemically stabilized are classified as treated subbase.

Table 58. Thickness of test-section layers in inches by the layer type.

GS = granular subbase; SHRP = Strategic Highway Research Program; TS = treated subbase
Note: All thickness values are expressed in inches.

## DI LINEAR REGRESSION

Table 59 shows the results of linear regression analysis performed on DI values calculated from FWD testing. The results show the $\Delta D I$ intercept $\left(\Delta D I_{i}\right)$, the initial $\Delta D I$ after the pavement was constructed and the $\Delta D I$ slope $\left(\Delta D I_{s}\right)$, the change in $\Delta D I$ per year after construction up to 10 years. Intercept and slope was also computed for DI values at FWD testing locations J1 (slab center) and J2 (slab corner).

Table 59. Linear regression intercepts and slopes for DI.

## LTE LINEAR REGRESSION

Table 60 shows the results of linear regression analysis performed on LTE values calculated from FWD testing. The results show the LTE intercept $\left(L T E_{i}\right)$, the initial LTE after the pavement was constructed and the LTE slope $\left(L T E_{s}\right)$, and the change in LTE per year after construction up to 10 years.

Table 60. Linear regression intercepts and slopes for LTE.

## RSTUDIO® RESULTS FROM LINEAR REGRESSION ANALYSIS OF CLIMATIC AND STRUCTURAL FACTORS TO PSG VALUES

Linear regression analysis computations were completed using RStudio, a free and open-source integrated development environment using the R programming language. ${ }^{(22)}$ The following linear model summaries (Figure 336 through Figure 341) are the results of using climatic and structural factors to predict the intercept and slope of PSG values $\left(P S G_{i}\right.$ and $\left.P S G_{s}\right)$. The interpretation of these models and the significance of their parameters are analyzed further in chapter 8 of this report. These modeling results are supplemental to that analysis.

Dependent variables included the following:

- $P S G_{i}=p s g_{-}$i_bfit
- $P S G_{s}=$ psg_s_bfit

Independent variables included the following:

- $T_{0}=$ temp_0
- $\Delta_{T 0}=$ temp_0_dif
- $H_{0}=$ hum_0

## RSTUDIO RESULTS FROM LINEAR REGRESSION ANALYSIS OF DI AND STRUCTURAL FACTORS TO PSG VALUES

Linear regression analysis computations were completed using RStudio. ${ }^{(22)}$ The following linear model summaries (figure 342 through figure 347) are the results of using climatic and structural factors to predict $P S G_{i}$ and $P S G_{s}$ values. The interpretation of these models and the significance of their parameters are analyzed further in chapter 9 of this report. These modeling results are a supplement to that analysis.

Dependent variables included the following:

- $P S G_{i}=$ psg_i_bfit
- $P S G_{s}=$ psg_s_bfit

Independent variables included the following:

- $\Delta D I_{i}=\mathrm{di} \_j 1 \_\mathrm{j} 2$ intercept
- $\Delta D I_{s}=$ di_j1_j2_regr
- $\left(D_{J I}\right)_{i}=$ di_j1_intercept
- $\left(D_{J l}\right)_{s}=$ di_j1_regr
- $\left(D_{J 2}\right)_{i}=$ di_j2_intercept
- $\left(D_{J 2}\right)_{s}=\mathrm{di} \mathrm{j} 2$ _regr
- $W_{\text {slab }}=$ slab_width
- $L_{\text {slab }}=$ slab_length
- $h_{P C}=\mathrm{pc}$ _thk
- $h_{G B}=$ gb_thk
- $h_{P A T B}=$ patb_thk
- $h_{L C B}=$ lcb_thk
- $h_{G S}=$ gs_thk
- $h_{T S}=$ ts_thk
- $P V=$ paste_vol
- $F=$ mod_rupt
- $E=$ mod_elast
- $\Delta T=$ temp_grad

Ca11:

## RSTUDIO RESULTS FROM LINEAR REGRESSION ANALYSIS OF LTE AND STRUCTURAL FACTORS TO PSG VALUES

Linear regression analysis computations were complete using RStudio. ${ }^{(22)}$ The following linear model summaries (figure 348 through figure 353) are the results of using climatic and structural factors to predict $P S G_{i}$ and $P S G_{s}$ values. The interpretation of these models and the significance of their parameters are analyzed further in chapter 9 of this report. These modeling results are a supplement that analysis.

Dependent variables included the following:

- $P S G_{i}=$ psg_i_bfit
- $P S G_{s}=$ psg_s_bfit

Independent variables included the following:

- $L T E_{i}=$ lte_intercept
- $L T E_{s}=$ lte_regr
- $W_{\text {slab }}=$ slab_width
- $L_{\text {slab }}=$ slab_length
- $h_{P C}=$ pc_thk
- $h_{G B}=\mathrm{gb}$ _thk
- $h_{P A T B}=$ patb_thk
- $h_{L C B}=$ lcb_thk
- $h_{G S}=$ gs_thk
- $h_{T S}=$ ts_thk
- $P V=$ paste_vol
- $F=$ mod_rupt
- $E=$ mod_elast
- $\Delta T=$ temp_grad

```

## APPENDIX J. AREAS OF LOCALIZED ROUGHNESS

## INTRODUCTION

Typical studies of pavement roughness and roughness progression address the average IRI over the road segments of interest. In most cases, studies do not examine the contributions of localized roughness to overall IRI. Many States that specify smoothness using the IRI include requirements on the average IRI over a standard length (e.g., 528 ft ) and on localized roughness. Per AASHTO R54-14, ALRs are defined as any region where the IRI averaged over a $25-\mathrm{ft}$ base length is greater than a specified threshold. ${ }^{(24)}$ Negative pay adjustments and requirements for corrective action are often based on the area of pavement out of compliance and the peak roughness value within the ALR. Typically, IRI and ALR are based on a single pass over the specified road segment.

The literature offers broad information about changes to average IRI values over time and statistical repeatability of IRI measurements produced by multiple passes over the same pavement section. However, little information is available regarding changes over time, seasonal, and diurnal changes in ALR of jointed PCC pavement or agreement in ALR between repeated profile measurements. This appendix presents examples of long- and short-term changes in ALR on jointed PCC test sections within the LTPP program and examines the repeatability of extent, severity, and placement of ALR.

The profile measurements discussed in this report offer a research-quality dataset for quantifying potential short- and long-term changes in ALR on five LTPP SPS-2 projects and five LTPP GPS-3 test sections. Long-term changes are examined using profile measurements by the LTPP program. These changes include annual visits (with few exceptions) to the GPS-3 sections starting in 1990 and to SPS-2 sites starting from the year each site was opened to traffic. Many of these sites and sections have been monitored over more than 20 years. Three of the GPS-3 sections and three of the SPS-2 sites also include sets of seasonal or diurnal measurements collected under the LTPP SMP. (Appendix B describes the monitoring history of each site and section in detail.)

Short-term changes are examined using profile measurements of the same SPS-2 sites and GPS-3 sections using profile measurements from an FHWA study of jointed PCC curl and warp conducted from 2003 to 2004. ${ }^{(85)}$ The study collected profile measurements over diurnal and seasonal cycles. Diurnal monitoring typically included profile-measurement visits before sunrise, after sunrise, in the midafternoon, and after sunset. Seasonal monitoring typically included four visits throughout a 12 -month period that approximated one visit per season. Of the 83 jointed PCC test sections included within the LTPP dataset, the FHWA study included seasonal and diurnal monitoring of 44 test sections and diurnal monitoring of another 20 test sections. The FHWA study did not include the remaining 19 test sections

Postprocessing of raw profile measurements from both sources removed minor inconsistencies in longitudinal offset and in the output of distance-measurement instruments (DMIs) among all measurements from each section. Researchers removed longitudinal offset between profile measurements by using cross-correlation of filtered profiles; a process called automated
synchronization. ${ }^{(2,11)}$ The DMI adjustment procedure ensured consistent longitudinal scaling among all passes over a given section. This process is equivalent to optimal DMI adjustment described by Perera and Karamihas. ${ }^{(105)}$

Each series from the FHWA curl-and-warp study included at least 7 and as many as 11 passes by the profiler. Seven or nine passes were common for the LTPP program. Researchers performed data-quality screening to select five repeat profile measurements per section from each series. Among the group of available runs, five measurements that exhibited the best agreement with each other were selected for further analysis. Agreement between two profiles was judged by cross-correlating the profiles after applying the IRI filter. ${ }^{(2,11)}$ Chapter 4 of this report describes the synchronization and quality-screening procedures in detail.

The quality-screening process sought five passes from each visit with the highest repeatability. The resulting repeatability in ALR represents the best case (i.e., research-quality fieldmeasurement procedures followed by rigorous synchronization and quality screening). The aligned profile data provided an opportunity to compare the extent and severity of ALR without variation caused by inconsistent longitudinal placement of profile features. Changes in ALR among repeat passes from the same visit are attributed to variations in lateral tracking of the profiler and limitations with height sensors and accelerometers. Additional changes in ALR between measurement visits are attributed to changes in the actual profile of the pavement.

## BACKGROUND

ALRs are derived from roughness profiles. Sayers originally proposed roughness profiles as a way to show the distribution of roughness in detail over the length of a road. ${ }^{(106)}$ Sayers recommended using roughness profiles for specifying "the quality of pavements after construction or repair, and the accuracy of profiling equipment." ${ }^{(107)}$ A roughness profile displays a continuous report of roughness averaged over a specified length as a function of distance along a particular road section. In contrast to discrete interval reporting of roughness, which provides a listing of roughness values for consecutive segments, a roughness profile provides the roughness of all possible segments of a given length. ${ }^{(107)}$

A roughness profile is calculated from an elevation profile. The calculation is detailed in the following three steps:

Step 1: Filter the elevation profile using the IRI algorithm. The IRI algorithm includes smoothing the profile by applying the moving average with a 9.84 -inch base length and filtering the profile using the Golden Car Model. ${ }^{(108)}$ The Golden Car Model is a quarter-car simulation with standard parameter values, and the predicted output used for the IRI is spatial velocity across the suspension. For engineering purposes, the IRI algorithm can be considered a filter that, when applied to an elevation profile, produces a trace in units of slope (e.g., inches $/ \mathrm{mi}$ ) and emphasizes content that causes vibration in passing vehicles.

Step 2: Rectify the filtered trace by taking the absolute value of each point.
Step 3: Apply a moving average to the rectified trace. The base length of the moving average corresponds to the desired segment length used for averaging.

Figure 354 through Figure 357 demonstrate the process on a profile of section 390204 measured 9.9 years after it was opened to traffic. Figure 354 shows the left elevation profile. The profile is high-pass filtered with a cutoff wavelength of 100 ft to make features that affect the IRI more visible. This is a jointed PCC section with a nominal joint spacing of 15 ft . The profile includes downward spikes at many joints.

Source: FHWA.
Figure 354. Graph. Left elevation profile of section 390204 at 9.9 years.
Figure 355 shows the outcome of step 1. The graph is the raw output of the IRI algorithm in units of inches $/ \mathrm{mi}$. The total range of values extends from -544 to 290 inches $/ \mathrm{mi}$. The most severe value occurs 106 ft from the start of the section, which is the location of a downward step in the elevation profile.

Raw IRI Filter Output (inches/mi)

Source: FHWA.
Figure 355. Graph. Raw IRI filter output of section 390204 at 9.9 years.
Figure 356 shows the outcome of step 2, which is obtained by taking the absolute value of each point in the trace from Figure 355 . The overall IRI for the entire $500-\mathrm{ft}$ section is 71.8 inches $/ \mathrm{mi}$ and is the average value of every point in this trace. For shorter segments within the section, the IRI is calculated by averaging the values within the desired range.

Figure 356. Graph. Rectified IRI filter output for section 390204 at 9.9 years.
Figure 357 shows the outcome of step 3 , which is the roughness profile for a base length of 25 ft . Each point in Figure 357 represents the IRI of a 25 - ft -long segment that begins 12.5 ft upstream and ends 12.5 ft downstream. Note that features of the profile outside the section boundaries affect the roughness values in the first and last 12.5 ft of the trace.

Source: FHWA.
Figure 357. Graph. Left roughness profile for section 390204 at 9.9 years.
The short-interval roughness profile shows how roughness is distributed along the section and whether any areas exist that contribute disproportionately to overall roughness. Any area in which the trace is greater than a designated threshold is considered an ALR. A threshold of 125 inches/mi is marked in Figure 357. Two areas violate this threshold. The first ranges from 99.2 to 105.1 ft with a peak value of 128.7 inches $/ \mathrm{mi}$ and the second ranges from 110.0 to 115.1 ft with a peak value of 130.5 inches $/ \mathrm{mi}$.

One tilted slab causes both ALRs that appear in Figure 357. Figure 358 shows a closeup view of the left elevation profile. Downward spikes are visible at three joints, including those at 99.1 and 114.5 ft from the start of the section. The slab between these joints is cracked, and the leading portion of the slab is tilted upward. The primary cause of the localized roughness is the 0.18 -inch fault at the midslab crack, which is 106.0 ft from the start of the section. The roughness profile
fluctuates between 99 and 115 ft because each point includes additional influence from other roughness within the $25-\mathrm{ft}$ averaging range. This example demonstrates the importance of inspecting the elevation profile to determine a cause once ALRs are identified.

## ALR SETTINGS

This study reports statistics that describe short- and long-term changes and repeatability of ALR using IRI from each wheel path, a base length of 25 ft , and threshold values of 125 inches/mi and 160 inches/mi. ALRs are primarily quantified in terms of total area. This section demonstrates the influence of alternative index options, base lengths, and methods of quantifying the extent and severity of ALRs.

## Base Length

The ALR detected from a profile is sensitive to base length. The maximum roughness observed in a roughness profile is expected to increase as base length decreases, and short base lengths reveal highly localized roughness averaged using longer base lengths. ${ }^{(106)}$ Figure 359 and Figure 360 provide an example from section 040213 measured 14.2 years after it was opened to traffic. Figure 359 shows the right elevation profile. The profile is high-pass filtered with a cutoff wavelength of 100 ft to make features that affect the IRI more visible. Section 040213 is jointed PCC with a nominal joint spacing of 15 ft . The profile includes evidence of upwardly curled slabs, which contribute to roughness throughout the test section. Deep narrow spikes appear in areas where the profiler passed over wandering longitudinal cracks, which make localized contributions to roughness.

Figure 360 compares the roughness profile corresponding to Figure 359 for base-length values of $10,25,50$, and 100 ft . The figures show that the range of values for the roughness profiles grows more extreme as base length decreases. At a base length of 100 ft , the highest values in the roughness profiles appear in areas that include the narrow dips at the longitudinal cracks. However, the influence of the dips is averaged by lower roughness in the surrounding area. As base length decreases, peak values in the roughness profiles increase, and the trace identifies the location of the localized roughness more closely.

## Right Elevation (inches)

Source: FHWA.
Figure 359. Graph. Right elevation profile of section 040213 at 14.2 years.

Source: FHWA.
Figure 360. Graph. Right roughness profiles of section 040213 at 14.2 years.
The average value of each trace in Figure 360 approximates the average IRI for the section of 145.0 inches $/ \mathrm{mi}$ to within $1 \mathrm{inch} / \mathrm{mi}$ because, except for end effects, the average value is independent of base length. "End effects" refers to roughness profiles including some influence from profile outside section boundaries within half of the base length at either end. Each trace has a slightly different average value because the range changes with base length. When the length of the section increases relative to the base length, the average value of the roughness profile more closely approaches the average IRI for the section.

Figure 361 provides an additional demonstration of the influence of base length on variations that appear in a roughness profile. The figure shows the cumulative probability distribution of roughness from each trace in Figure 360. The distribution is shown in length rather than percentage. The total range of roughness values increases as base length decreases. For example, the values range from 104.0 inches $/ \mathrm{mi}$ to 210.8 inches $/ \mathrm{mi}$ at a base length of 100 ft and from 24.6 inches $/ \mathrm{mi}$ to 640.1 inches $/ \mathrm{mi}$ at a base length of 10 ft .

Source: FHWA.
Figure 361. Graph. Cumulative roughness of section 040213 at 14.2 years.
Figure 361 presents a potential summary of the localized roughness that exists within a long pavement section. For a given base length and roughness threshold, the cumulative distribution provides the total extent of ALR, which can be presented in length, as shown, or percentage.

For the highly localized narrow dips shown in Figure 359, base lengths of 10 and 25 ft pinpointed the roughness source more closely. A short base length is often desirable to detect localized rough features and quantify their severity. Karamihas et al. recommended a minimum base length of 25 ft and warned that for very short base lengths, such as 10 ft , height-sensor dropouts and other sensor errors were more likely to register as ALR. Additionally, peak roughness in an ALR was likely to vary between profiler types depending of the details of the sample procedures and height-sensor footprint. ${ }^{(109)}$ Sayers recommended using a 20 - ft base length for detecting localized roughness, but that the base length should be shorter than the minimum distance between rough features. ${ }^{(106)}$

Figure 362 through Figure 364 demonstrate the need to consider the source of roughness when selecting an appropriate base length for detecting ALR. Figure 362 shows the left elevation profile for an area of section 133019 measured approximately 22.7 years after it was constructed. The profile is high-pass filtered with a cutoff wavelength of 100 ft to make features that affect the IRI more visible. Section 133019 is jointed PCC with a nominal joint spacing of 20 ft . Each slab shown has a net downward curvature, and the most severe roughness appears as dips at the joints.

Figure 363 shows the roughness profile for a base length of 10 ft over the same range of section 133019 shown in Figure 362. The arrows indicate the joint locations. Localized roughness is registered at each joint. The center of each area in the roughness profile with the highest magnitude is shifted slightly from the joint locations. The shift occurs because the IRI algorithm reacts to the roughness starting at each rough feature and over a short distance past the joint locations.

Figure 364 shows the roughness profile for a base length of 25 ft with arrows at each joint location. Using this base length, the peak values in the roughness profiles appear between the joints and some of the lower roughness values appear at the joints because the base length is greater than the spacing between the positions of localized rough features. At the center of each slab, the $25-\mathrm{ft}$ range used to calculate roughness values includes two of the joints. The roughness within 7.5 ft of each joint includes the influence of only one joint.

Source: FHWA.
Figure 363. Graph. Left roughness profile of 10-ft base length for section 133019 at 22.7 years.

Source: FHWA.
Figure 364. Graph. Left roughness profile of $\mathbf{2 5}$-ft base length for section 133019 at 22.7 years.

A longer base length may be useful for identifying rough areas in a long section of roadway. When evaluating miles of pavement, a roughness profile with a base length of 528 ft provides a way to identify areas that need attention. For example, the format of the pay adjustment schedule recommended by AASHTO R54-14 is based on roughness profiles calculated using a base length of $528 \mathrm{ft} .{ }^{(24)}$ Swan and Karamihas demonstrated the use of roughness profiles with a base length of 264 ft for general pavement acceptance and 25 ft for investigation of roughness within areas that do not meet the specification. ${ }^{(107)}$

This research examines $500-\mathrm{ft}$-long sections. The 500 - ft length imposes a limit on base length. Figure 365 provides an example of using a relatively long base length on a short section to quantify the functional aspects of pavement behavior. Figure 365 shows the right roughness profile from section 040214 measured 10.4 years after it was opened to traffic. The roughness profile was calculated using a base length of 100 ft . The average IRI for this profile is 89.1 inches $/ \mathrm{mi}$. This section is roughest over the first 100 ft with a peak value of 164.2 inches $/ \mathrm{mi}$. The roughness decreases over the next 200 ft and is lowest over the last 200 ft with values of 70.7 inches $/ \mathrm{mi}$ or less and a minimum value of 48.8 inches $/ \mathrm{mi}$.

Source: FHWA.
Figure 365. Graph. Right roughness profile of section 040214 at 10.4 years.

A change in slab curl and warp throughout the section causes the change in roughness shown in Figure 365. Section 040214 is jointed PCC with a nominal joint spacing of 15 ft . The slabs have downward curvature in the first 300 ft of the section, and the magnitude of the curvature decreases along the section. In the last 200 ft of the section, the slabs are relatively flat. (The Spatial Trends section in chapter 5 provides more information.)

## Index Options

The preceding examples present roughness profiles and ALR derived from IRI in either the left or right profile. Two other options for identifying ALR include the following:

- MRI: The average of the IRI from the left and right wheel paths. An MRI-based roughness profile is calculated using a point-by-point average of the roughness profile from the left and right wheel path.
- HRI: The profiles are combined using point-by-point averages of the elevation values from the two sides. An HRI-based roughness profile is calculated after passing the combined profile through the IRI algorithm.

MRI or HRI moderate localized roughness that appears on only one side of the lane or is much rougher on one side than the other. HRI is always less than or equal to MRI because averaging the elevation profiles eliminates aspects of fluctuations in elevation that are not consistent on both sides. HRI preserves the bounce component of roughness but eliminates the roll component.

Figure 366 through Figure 368 demonstrate the potential contrast to the IRI from individual wheel paths of HRI and MRI. Figure 366 shows the left elevation profile for section 040213 measured 14.2 years after it was opened to traffic. The profile is high-pass filtered with a cutoff wavelength of 100 ft to make features that affect the IRI more visible. This profile was measured in the same pass as the right elevation profile shown in Figure 359, and Figure 359 and Figure 366 have compatible vertical scaling. Profiles from both sides include upwardly curled slabs, which introduced roughness with features similar in each wheel path. Profiles from both sides also include a long wavelength disturbance in the first 150 ft for the test section. However, open longitudinal cracks do not appear in the left side of the lane, and the left elevation profiles do not include the patches of downward spikes that appear in Figure 359.

Left Elevation Profile (inches)

Source: FHWA.
Figure 366. Graph. Left elevation profile of section 040213 at 14.2 years.
Figure 367 shows the roughness profiles for both wheel paths using a base length of 25 ft . Figure 367 identifies a threshold of 150 inches $/ \mathrm{mi}$. With this threshold, the left profile includes eight

ALRs with a total length of 157.9 ft , and the right profile includes seven ALRs with a total length of 41.9 ft .

Source: FHWA.
Figure 367. Graph. Left and right roughness profiles for section 040213 at 14.2 years.
Table 61 lists the boundaries, length, and peak roughness for each ALR. The table also lists excess roughness (ER), which is discussed in the following section. The most severe localized roughness appears in areas of the right wheel path in which narrow dips were measured over the opened longitudinal cracks. The left wheel path registers several ALRs with relatively lower peak roughness, which do not correspond to individual surface defects. Upwardly curled slabs contribute to roughness but not sufficiently in the first 70 ft or the last 300 ft of the test section. ALRs only appear where the distributed contribution of the long-wavelength disturbance shown in Figure 366 exacerbates the roughness.

Figure 368 shows the MRI- and HRI-based roughness profiles using a base length of 25 ft and a marked threshold value of 150 inches $/ \mathrm{mi}$. These roughness profiles were derived from the same elevation profiles as Figure 367 and are displayed with vertical scaling compatible with Figure 368. Figure 368 shows that averaging across both wheel paths moderates the effects of the severe roughness that appear on the right side. Averaging greatly reduces the values of peak roughness values and eliminates the ALR from the first 55 ft of the section. The ALR in the last 50 ft of the right roughness profiles are eliminated in the HRI profile and are nearly eliminated in the MRI profile.

Table 61. ALR in left and right profiles for section 040213 at 14.2 years.

| Side | ALR Start (ft) | ALR End (ft) | ALR Range (ft) | Peak Roughness <br> (Inches/mi) | ER (Inches/mi) |

Source: FHWA.
Figure 368. Graph. MRI- and HRI-based roughness profiles for section 040213 at 14.2 years.

The ALR for MRI and HRI are listed in Table 62. With a threshold of 150 inches/mi, the MRI profile included six ALRs with a total length of 107.9 ft . The HRI profile showed lower values than the MRI profile throughout the section. The HRI profile included six ALR due to the area of roughness that straddles the threshold line in the range from 150 to 175 ft . Using HRI, the total length is reduced to 70.7 ft , the peak roughness values are reduced, and the ALR from 180 to 205 ft is eliminated.

Table 62. ALR derived from MRI and HRI profiles for section 040213 at 14.2 years.

| Index | ALR Start (ft) | ALR End (ft) | ALR Range (ft) | Peak Roughness <br> (Inches/mi) | ER (Inches/mi) |
| :---: | :---: | :---: | :---: | :---: | :---: |
| MRI | 91.0 | 93.0 | 2.0 | 152.4 | $<0.01$ |
| MRI | 121.2 | 174.1 | 52.9 | 247.7 | 4.68 |
| MRI | 181.6 | 203.9 | 22.4 | 177.2 | 0.47 |
| MRI | 312.0 | 312.5 | 0.5 | 150.3 | $<0.01$ |
| MRI | 313.8 | 342.2 | 28.4 | 218.2 | 1.82 |
| MRI | 480.2 | 482.0 | 1.7 | 152.5 | $<0.01$ |
| HRI | 91.1 | 92.4 | 1.3 | 151.5 | $<0.01$ |
| HRI | 121.8 | 150.8 | 29.0 | 247.5 | 3.68 |
| HRI | 152.9 | 156.5 | 3.5 | 155.4 | 0.02 |
| HRI | 158.5 | 162.3 | 3.8 | 155.6 | 0.03 |
| HRI | 164.4 | 173.6 | 9.2 | 160.4 | 0.08 |
| HRI | 316.8 | 340.7 | 23.9 | 203.3 | 1.17 |

Using MRI or HRI offers an advantage because it reduces the amount of data to assimilate by half. Each index captures the most severe localized roughness. However, neither index offers information about whether the source of roughness exists on one side of the lane or both. In contrast, analyzing roughness profiles from both wheel paths helps identify the sources of roughness. A higher threshold is needed for ALRs based on MRI than for IRI from individual wheel paths for capturing the features that cause the same reduction in functional quality. The HRI is not as sensitive as IRI to features that are not the same on each side of the lane (e.g., a bump on one side and a dip of the same layout and shape on the other side). As a result, HRI-based roughness profiles will underestimate the reduction in functional quality caused by some features, requiring an even higher threshold for capturing the features that cause the same reduction in functional quality.

## OPTIONS FOR QUANTIFYING LOCALIZED ROUGHNESS SEVERITY

Table 61 and Table 62 demonstrate three possible methods for quantifying the severity of localized roughness: number of ALRs, total length of ALRs, and peak roughness values. Practical application of roughness profiles for project-level pavement assessment typically requires using all three.

Table 61 shows that the number of ALRs does not characterize the severity of localized roughness. The left and right wheel paths included the same number of ALR, although the overall length and severity of ALR was much greater for the right wheel path. However, the number of ALRs may be of interest if corrective action is required for ALRs. The number and layout of ALRs may also be of interest if corrective action is permitted to reduce negative pay adjustment or if ALRs are used to plan surface rehabilitation.

For planning corrective action or rehabilitation, further viewing and analysis of the elevation profiles is needed to identify the sources of roughness and apply options for reducing roughness cost effectively. For example, Figure 357 and Figure 358 demonstrated a case in which more than one ALR corresponded to the same surface defect. Figure 366 and Figure 367 showed a case in which two sources of background roughness distributed over a length greater than the base length caused several ALRs. A corrective strategy based on addressing the eight ALRs
individually is likely to be less effective than a corrective strategy based on mitigating the long-wavelength disturbance or roughness at the joints associated with upward curl.

The total length of ALR provides a suitable summary of the status of a pavement section in some cases but not others. Normalized by section length, the total length of ALR defines the proportion of the section out of specification, which offers a simple way to compare the status of pavement sections. However, the total length of ALR does not capture potential variations in the severity of roughness. For example, based on total length, the eight ALRs listed for the left wheel path in Table 61 incorrectly implies a greater reduction in the health of the pavement than the area listed for the right wheel path from 310.0 to 345.4 ft . The eight ALRs for the left wheel path have a total length of 41.9 ft , and the highest peak value is 178.2 inches $/ \mathrm{mi}$. The ALR from 310.0 to 345.4 ft in the right wheel path has a smaller length but a much higher peak roughness value of 301.9 inches $/ \mathrm{mi}$.

In contrast to the number and length of ALR, peak roughness values provide a measure of the severity of localized roughness but no measure of the extent. The use of peak roughness requires the analyst to consider a potentially large number of values. Weighting the length of ALRs by their severity provides an alternative that may help prioritize investment in corrective action or assign negative pay adjustments based on degradation in functional quality. The following example is similar to the provisions for calculating negative pay adjustments for localized roughness in AASHTO R54-14. ${ }^{(24)}$

Figure 369 shows the distribution of roughness for left and right roughness profiles of section 040213 , measured 14.2 years after it was opened to traffic. The distribution is weighted by length. These plots show the distribution of roughness that appears in each trace from Figure 367. This distribution sorts roughness into discrete bins with an increment of 5 inches $/ \mathrm{mi}$. The horizontal line marks an example roughness threshold of 150 inches $/ \mathrm{mi}$. For each wheel path, the sum of the length for bins above 150 inches $/ \mathrm{mi}$ is equal to the total length of ALR for each wheel path. (The total length of ALR is proportional to the area left of the curve and above the threshold line.)

Table 63 shows the estimated ALR weighted by severity. The table lists six nonzero bins with roughness above 150 inches/mi for the left wheel path (Figure 369). Each value of roughness above the threshold is the center of the corresponding range, which is the value at the center of the bin within the distribution minus the roughness threshold. Roughness-weighted length for each range is the product roughness above the threshold and length. The total value of $468.4 \mathrm{ft} \times$ inches $/ \mathrm{mi}$ is calculated from the probability distribution, but it is also the total roughness-weighted length for all ALRs within the test section. The roughness-weighted length is an estimate of the area above and below the threshold line by the left roughness profile in Figure 367.

Table 63. ALR severity for section 040213 at 14.2 years for the left wheel path.

| Roughness Range <br> (Inches/mi) | Length (ft) | Roughness Above <br> Threshold (Inches/mi) | Roughness-Weighted <br> Length (ft×Inches/mi) | ER (Inches/mi) |
| :---: | :---: | :---: | :---: | :---: |
| $150-155$ | 11.06 | 2.5 | 27.6 | 0.055 |
| $155-160$ | 11.96 | 7.5 | 89.7 | 0.179 |
| $160-165$ | 5.34 | 12.5 | 66.7 | 0.133 |
| $165-170$ | 6.94 | 17.5 | 121.5 | 0.243 |
| $170-175$ | 3.86 | 22.5 | 86.8 | 0.174 |
| $175-180$ | 2.76 | 27.5 | 76.0 | 0.152 |
| $>150$ | 41.91 | - | 468.4 | 0.937 |

-No data.
Roughness-weighted length summarizes the severity of ALRs for a test section in a way that incorporates length and peak roughness. However, the units of $\mathrm{ft} \times$ inches $/ \mathrm{mi}$ are not intuitive, and the value grows in proportion to section length for the same density of localized roughness. The excess roughness (ER) column in Table 63 lists the contribution from each roughness range. The ER is the roughness-weighted length normalized by the section length, which is 500 ft . (This could have been calculated directly if fFigure 369 and the Length column of Table 63 were expressed in terms of probability rather than length.) The total excess roughness (TER) is 0.937 inches $/ \mathrm{mi}$ for the left wheel path, which is the total roughness-weighted length normalized by the section length and quantifies the contribution of ER to the average roughness of the section. Reducing the roughness within all ALR to the threshold value would reduce the overall IRI by 0.937 inches $/ \mathrm{mi}$.

Calculation of roughness-weighted length for the right wheel path includes contributions from 41 bins (from 150 to 355 inches $/ \mathrm{mi}$ ), and produces a total of $9,614.2 \mathrm{ft} \times$ inches $/ \mathrm{mi}$. This produces an estimate of TER of 19.228 inches $/ \mathrm{mi}$. As such, localized roughness greater than the threshold accounts for an increase in the sectionwide IRI of 0.94 inches $/ \mathrm{mi}$ for the left wheel path and 19.23 inches $/ \mathrm{mi}$ for the right wheel path. This TER estimate is less than the total contribution of
the corresponding features of the elevation profile to roughness. It only accounts for the portion of the roughness above 150 inches $/ \mathrm{mi}$ in the roughness profile.

An equivalent calculation of TER is possible using the roughness profile directly. The TER is the sum of the ER at every point in the profile $\left(R_{E, i}\right)$ times the profile recording interval $(\Delta x)$ and normalized by the section length $\left(L_{S}\right)$, as shown in figure 370 .

$$
T E R=\frac{1}{L_{S}} \sum_{i=1}^{N} \Delta x \cdot R_{E, i}
$$

## Figure 370. Equation. TER.

In the equation in figure $370, N$ is the number of points in the roughness profile and $i$ is the point index. ER at a given point is calculated as shown in figure 371.

$$
R_{E, i}=\max \left(0.0, R_{i}-R_{T}\right)
$$

Figure 371. Equation. ER at a point.
In the equation in figure $371, R_{i}$ is the value of the roughness profile at point $i, R_{T}$ is the roughness threshold, and the max function returns the more positive value among its inputs. Note that only those points in the roughness profile greater than the threshold roughness contribute to the sum in the equation in figure 370. The profile recording interval is constant and the $L=N \times \Delta$ calculation of TER is simplified by the equation shown in figure 372.

$$
T E R=\frac{1}{N} \sum_{i=1}^{N} \max \left(0.0, R_{i}-R_{T}\right)
$$

Figure 372. Equation. Simplified TER.
For the roughness profiles shown in Figure 367 and summarized in Figure 369, TER calculation includes 7,777 points. The sum includes 652 nonzero points for the left roughness profile, which corresponds to a total ALR length of 41.9 ft , and 2,456 nonzero points for the right roughness profile, which corresponds to a total ALR length of 157.9 ft . TER values for the left and right are 0.927 and 19.22 inches $/ \mathrm{mi}$, respectively. These values are more precise than the values calculated from the roughness distribution because those values sorted roughness values into discrete bins.

With minor modification, the expression in figure 372 quantifies the relative severity of each ALR on a standard scale. ER for an individual area is calculated as shown in figure 373.

$$
E R=\frac{\Delta x}{L_{S}} \sum_{i=N_{S}}^{N_{E}}\left(R_{i}-R_{T}\right)
$$

Figure 373. Equation. ER for an ALR.
In the equation in figure $371, \Delta x$ is the recording interval, $R_{i}$ is the value of the roughness profile at point $i$ and $R_{T}$ is the roughness threshold, $N_{S}$ is the index of the first value above the threshold
for the $\mathrm{ALR}, N_{E}$ is the index of the last value above the threshold for the ALR, and $L$ is a standard section length of 528 ft .

ER is normalized by 528 ft to cast ALR severity onto a constant scale. ALR of equal roughness density will produce the same ER value regardless of actual section length. ER quantifies the roughness above the threshold of an ALR in terms of its contribution to the overall IRI of a $528-\mathrm{ft}$ long section. Table 61 and Table 62 list the ER for each ALR. Using ER distinguishes ALR based on both area and peak roughness level and helps identify the ALR that most affects overall roughness and functional quality.

## SHORT-TERM CHANGES

This section presents short-term changes in ALR for 59 LTPP SPS-2 test sections and 5 LTPP GPS-3 test sections. Data were collected in 2003 and 2004 to support an FHWA study of jointed concrete curl and warp. ${ }^{(85)}$

The FHWA study included diurnal measurements of 19 test sections and diurnal and seasonal measurements of 19 additional test sections distributed throughout the United States. ${ }^{(85)}$ The analysis was performed on a subset of measurements collected on LTPP test sections, which include GPS-3 test sections 063021, 133019, 183002, 273003, and 493011, and SPS-2 test sections $040217,040219,200205,200207,370201,390209,390211,530206$, and 530207. Raw profile measurements at the five SPS-2 sites often included coverage of 50 additional test sections incorporated into this study.

Profile data included measurements over a diurnal cycle in every visit to the SPS-2 sites and GPS-3 sections. Diurnal profile measurements included four series of passes over a 24 -hour cycle: before sunrise, after sunrise, midafternoon, and after sunset. The diurnal cycle did not always begin before sunrise. For example, the earliest visit to section 063021 began with a series of measurements after sunset, which was followed by the other three visits the next day. Profile data include seasonal measurements of three of the SPS-2 sites and four of the GPS-3 sections. Seasonal measurements occurred in four visits over a 1-year cycle, and each seasonal measurement visit included measurements over a diurnal cycle.

Table 64 and Table 65 list the SPS-2 sites and GPS-3 sections, respectively. The tables list the measurement dates and timing of the first pass in each of the diurnal series. A typical series of passes occurred over 50-80 minutes at SPS-2 sites, although some took up to 2 hours. A typical series of passes occurred over an hour or less at GPS-3 sections. Each series included at least seven repeat profile passes. Five passes from each series were selected for analysis based on agreement in profile, as described in the Quality Screening section of chapter 4.

Table 64. Measurement dates and times for SPS-2 sites.

$\mathrm{BD}=$ before dawn; $\mathrm{AD}=$ after dawn; $\mathrm{MA}=$ midafternoon; $\mathrm{AS}=$ after sunset.
Table 66 lists the average roughness in the right wheel path for the five repeat passes selected from each diurnal and seasonal series. The table lists the age of each section on the date of the earliest visit. For the SPS-2 sites, the age is the time in years since the open to traffic date. For the GPS-3 sections, the age is the time in years since the date of construction. The seasonal test sections were not actually visited once per season; rather, they were visited once in each of four consecutive time slots ranging from July to September 2003, October to December 2003, January to March 2004, and April to June 2004. Table 66 shows raw measurements lacked the
range to include section $040262,200203,200204,390203,390207,390208,390262,390263$, and 390265 in one of the four seasonal visits. Data were not collected after sunset at the North Carolina SPS-2 site.

As shown in Table 66, the overall IRI of many test sections changes over seasonal and diurnal cycles. Most of the cyclic change in roughness is attributed to cyclic changes in curl and warp. Cyclic changes in the extent and severity of ALR are likewise linked to changes in curl and warp. Changes in curl and warp are attributed to changes in environment, which induce changes in the temperature and moisture gradient throughout the depth of PCC slabs.

Note that the same profiler collected all measurements. Data collection included an effort to capture diverse environmental conditions. However, the specific dates of the measurements were influenced by the need to complete a data-collection cycle by the profiler and its crew that covered these and many other sections in a cost-effective circuit. As such, the conditions throughout the diurnal visits do not necessarily represent the maximum potential for cyclic changes in roughness. The changes observed on these 64 test sections represent examples of the changes that may occur.

Diurnal changes in IRI from the right wheel path of 25 inches/mi or greater were observed on sections 040222 , 040262, 200205, 273003, 493011, and the odd-numbered sections from the Arizona SPS-2 site. Odd-numbered SPS-2 sections have lower flexural strength than evennumbered sections. Sections 200205 and 273003 have slabs with downward curl. Their roughness is lowest before dawn and after sunset. The other sections have upward curl, and their roughness is highest before dawn and after sunset.

The 11 sections with large diurnal changes in roughness also exhibited large seasonal changes. Sections 390202 , 390204,390204 , and 390207 also showed a seasonal change. The slabs within these sections shifted toward downward curl in the final (i.e., summer) seasonal visit. The change in curl was either a reduction in upward curl, a reverse in the direction of curl, or an increase in downward curl.

Table 66. Average IRI by visit for the right wheel path.

Table 67 through Table 69 quantify sectionwide ALR for the right wheel path in several ways. Similar to overall roughness, the extent and severity of ALR is heavily influenced by curl and warp. However, the values in Table 67 through Table 69 do not directly correlate to the overall roughness values provided in Table 66 because the roughness threshold determines which features affect the extent, severity, and presence of ALR. In many cases, ALRs appear at a small number of rough features. As such, interactions with changes in curl and warp only depend on the behavior of a few slabs.

Table 67 lists the total ALR length (in feet) for each visit for a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. These values are the average sectionwide ALR length for five visits from each series. Several test sections have no ALR when the threshold value is set at 125 inches $/ \mathrm{mi}$ and the corresponding table entry is zero. In most cases, these are the sections with the lowest overall IRI values. For example, no visit with average IRI less than 64.7 inches/mi produced any ALR. Every visit with average IRI greater than 80.2 inches $/ \mathrm{mi}$ produced at least one ALR.

Any series with an average overall IRI above roughness threshold has a commensurately high total ALR length. The lowest total ALR length for a series with an average IRI of 125 inches/mi or above is 123 ft .

Table 68 lists the total ALR length (in feet) for each visit for a base length of 25 ft and a roughness threshold of 160 inches $/ \mathrm{mi}$. Results are provided for a higher threshold to show the change in ALR as threshold rises. For some sections with a longer service history, a threshold of 160 inches/mi may be more appropriate. Other sections simply have high roughness. Of the 736 series of runs quantified in Table 67 and Table 68, 152 had at least one ALR for a threshold of 125 inches $/ \mathrm{mi}$ but none for a threshold of 160 inches $/ \mathrm{mi}$.

Table 67. Total ALR length of the right wheel path at $125-\mathrm{inch} / \mathrm{mi}$ threshold.

-No data.
$\mathrm{BD}=$ before dawn; $\mathrm{AD}=$ after dawn; $\mathrm{MA}=$ midafternoon; $\mathrm{AS}=$ after sunset.
S1 = May 2003; S2 = Jul-Sep 2003; S3 = Oct-Dec 2003; S4 = Jan-Mar 2004; S5 = Apr-Jun 2004.

Figure 374 through Figure 379 provide graphical examples of short-term changes in total ALR length. Figure 374 shows the total ALR length for the right wheel path in each visit to section 040223 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. The measurements included a diurnal cycle within each seasonal set of visits. ALR length was largest in the predawn visit and lowest for the midafternoon visit in each season. The highest total ALR length for a midafternoon visit was 22 ft , and the lowest ALR length for a predawn visit was 116 ft .

The slabs within section 040223 were curled upward. Slab curl was typically the most severe at night and less severe at midday. Changes in slab curl account for the large range on overall IRI values of 87-125 inches $/ \mathrm{mi}$ and the large range in overall ALR length of 6-270 ft for a roughness threshold of 125 inches $/ \mathrm{mi}$. Table 67 and Table 68 show several sections that exhibited similar behavior because of diurnal changes in upward curl.

Source: FHWA.
Figure 374. Graph. Total ALR length of section 040223 for the right wheel path.
Figure 375 compares ALR behavior of the midafternoon visit on 02-Jun-2004 to the predawn visit on the following day. The figure shows the total ALR length from the right wheel path versus roughness threshold for one pass from each visit using a base length of 25 ft . Both traces have the same shape but are offset from each other by approximately 30 inches $/ \mathrm{mi}$. On section 040223 , the increase in upward curl at night increased the roughness by about 30 inches $/ \mathrm{mi}$ throughout its length. The increase in upward curl did not introduce localized roughness; rather, it exacerbated the existing localized roughness within the section.

Figure 376 shows the total ALR length for the right wheel path in each visit to section 200202 using a base length of 25 ft and a roughness threshold of 100 inches $/ \mathrm{mi}$. Similar to section 040223, section 200202 exhibited diurnal changes in roughness due to changes in the severity of upward curl. The overall IRI for the right wheel path had a minimum value of 52 inches $/ \mathrm{mi}$ for the midday visit on 04-Sep-2003. The IRI for the right wheel path for the predawn visit on

20-Apr-2004 was 78 inches $/ \mathrm{mi}$, a 50-percent increase. A noteworthy feature of the data in Figure 376 is the contrast between more than 80 ft of total ALR length for two of the visits and the absence or near absence of ALR in four others.

Figure 375. Graph. Cumulative ALR length of section 040223 for the right wheel path.

Source: FHWA.
Figure 376. Graph. Total ALR length of section 200202 for the right wheel path.
Figure 377 shows the total ALR length for the right wheel path in each visit to section 200205 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. Slabs within this section were curled downward. Within each seasonal group, total ALR length and overall IRI were the highest for the midafternoon visit and lowest for visits prior to 10:00 a.m.

Figure 377 includes evidence of potential seasonal changes in ALR length. By seasonal group, September 2003 measurements had the lowest ALR length and March 2004 measurements had the highest. Higher temperatures or greater moisture under the slabs in autumn and lower temperatures or lower moisture under the slabs in the spring may explain the difference. However, the true seasonal change is difficult to distinguish from diurnal effects.

Source: FHWA.
Figure 377. Graph. Total ALR length of section 200205 for the right wheel path.
Figure 378 shows the total ALR length for the right wheel path in each visit to section 390204 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. In the portions of the test section that account for most of the ALR, slabs were curled upward. Figure 378 shows ALR length was largest in autumn and winter. Within those seasonal groups, ALR length was largest in the predawn visits and after-dawn visits prior to 10:00 a.m. ALR length was much smaller (or zero) in summer and autumn.

Figure 379 compares ALR behavior of the predawn visit on 25-Jan-2004 to the predawn visit on 16-Jun-2004. The figure shows the total ALR length from the right wheel path versus roughness threshold for one pass from each visit using a base length of 25 ft . The change of roughness threshold associated with a given ALR length did not appear as a uniform shift in the traces shown in Figure 375. Instead, a greater range of roughness existed throughout the section for the profile measured in January 2004. The tail of the total ALR length distribution at high roughness values corresponds to the most severe ALRs.

The increase in overall roughness and ALR in winter is caused by an increase in upward slab curl. However, the change was not uniform throughout the section. The difference in upward curl in January 2004 appeared as severe uplift at specific joints within the last 200 ft of the section when compared to profiles collected in June 2004. The slab curl and the resulting roughness changed less in the first 300 ft of the section, and the severity of the downward fault shown in Figure 358 did not change.

Figure 379. Graph. Cumulative ALR length of section 390204 for the right wheel path.
The examples in this section address short-term changes in total ALR length. On most test sections, short-term changes in ER follow the same qualitative trends as total ALR length. However, the quantitative changes in ER are typically larger in terms of percentage.

Table 69 lists the average ER in the right wheel path for the five repeat passes selected from each diurnal and seasonal series. These values correspond to a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$.

## LONG-TERM CHANGES

This research examined long-term changes in ALRs for 78 LTPP SPS-2 test sections and 5 LTPP GPS-3 test sections. Data were collected for the LTPP program as described in appendix B. Profile data were collected approximately once per year since the open to traffic date at the SPS-2 sites. GPS-3 sections were monitored in at least 12 and at most 39 visits since 1989. Three GPS-3 sections and three SPS-2 sections were in the LTPP SMP. Profile data were collected over some seasonal cycles and at various times of day at SMP sections. In addition, data were collected at various times during a 24-hour cycle at each SPS-2 site in 2014.

No common long-term trend in ALR length or severity emerged among the 83 test sections. However, when researchers examined the test sections using a base length of 25 ft and roughness thresholds of 125 inches $/ \mathrm{mi}$ and 160 inches $/ \mathrm{mi}$, most test sections exhibited one or more of the following behaviors:

- Little or no ALR: In many cases where overall IRI remained low relative to the roughness threshold throughout the monitoring period, little or no ALR appeared.
- Stable ARL: Several test sections included a similar length of ALR throughout the monitoring history. ALRs typically appeared as a discrete, persistent set of rough profile features on these sections. In some cases, the severity of each ALR was also consistent over time.
- ALR growth with age: Several test sections included little or no ALR in the earliest monitoring visits, but ALR length and severity increased as distress and other sources of roughness increased over time.
- Confounded ALR growth: On some test sections, ALR length and severity increased over time. However, the trend was confounded by seasonal and diurnal fluctuations in curl and warp.

This section presents ALR length, severity, and locations over the monitoring history for eight test sections. These sections represent typical long-term trends for test sections that included ALR for threshold values of 125 inches/mi or higher. For each example, three graphs are provided:

- Bar charts, total ALR length: These figures show the total length for all ALR within the test section at the date and time of each measurement visit. Values of length are the average for the (typically five) repeat profile measurements from each visit.
- Bar charts, ALR severity: These figures show the ER within the test section at the date and time of each measurement visit. Values of ER are the average for the (typically five) repeat profile measurements from each visit. ER is the contribution to the overall IRI of all roughness above the threshold within the roughness profile.
- ALR map: These figures show the range of ALR for each profile-measurement pass. ALRs are marked with a line over the corresponding range, and no markings appear in ranges without localized roughness. Passes are grouped by profile-measurement visit to compare the locations of ALR borders between repeat passes.

All three graphs display the dependent variable (length, severity, or locations) along a horizontal axis. Measurement visits are stacked vertically and are arranged in order of occurrence with the
earliest visit at the top. The interval between visits is not consistent for the eight test sections. In some cases, visits are a year or more apart. In others, up to four monitoring visits occurred in one year or over one 24 -hour cycle.

Figure 380 through Figure 382 characterize the long-term trend in ALR for the right wheel path of section 040223 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. ALR length and ER increase over time. Both quantities are higher in the final monitoring visits than in the earliest monitoring visits. However, diurnal changes in slab curl cause greater variation in roughness than long-term changes.

The largest observations of ALR length and ER occurred between midnight and 3:00 a.m. on 13-Aug-2006 and 20-Sep-2008. This was when upward curl had the highest magnitude, which increased the average roughness to values near the threshold (Figure 380). Many of the ALR are not localized because their peak values did not exceed the average roughness for the section by more than 40 percent. As a result, ALR length stands out relative to other visits more so than ER because peak value at each ALR is not extreme compared to the average.

Four visits starting on 06-Feb-2014 demonstrate diurnal changes in ALR on section 040223 linked to upward slab curl. The roughness, ALR length, and ER were highest at night and early morning when the pavement surface was coolest and lower in the early afternoon and midafternoon when the pavement surface was warm.

Figure 383 through Figure 385 characterize the long-term trend in ALR for the right wheel path of section 370202 using a base length of 25 ft and a roughness threshold of 125 inches/mi. ALR length and ER may have undergone a modest long-term increase. However, cyclic changes in roughness caused by slab curl and warp obscure the long-term trend.

Monitoring visits to section 370202 include measurements in five consecutive seasons starting in October 1997. In the first four seasons, all profile measurements were collected between 10:30 a.m. and 3:15 p.m. For these visits, the average level of slab curl was neutral (PSG near zero) and the overall roughness in the right wheel path only varied from 81.9 to 83.0 inches $/ \mathrm{mi}$. (The range of age from 3.27 to 4.06 years is detailed in Figure 207 and Table 71.) In November 1998, profile measurements began at 8:45 a.m. For this visit, most of the slabs were curled upward. The ALR length and ER were much greater for this visit, and the overall roughness increased to 110.9 inches $/ \mathrm{mi}$ in the right wheel path. Similar onset of upward curl and commensurate increases in roughness were observed for measurements at about 9:00 a.m. on 14-Jul-2001 and 11-Oct-2001.

Figure 385. Graph. ER of section 370202 for the right wheel path.
Figure 386 through Figure 388 characterize the long-term trend in ALR for the right wheel path of section 370208 using a base length of 25 ft and a roughness threshold of 160 inches $/ \mathrm{mi}$. ALRs appeared in three specific locations in the earliest visits and remained throughout the monitoring history. Four additional ALRs appeared as the pavement aged. No distress was recorded at the
locations of these ALRs, and the specific sources of roughness were difficult to discern by viewing the profiles.

Section 370208 provides another example of seasonal and diurnal changes in slab curl making the long-term trend in ALR difficult to identify. Plots for this section were provided because the monitoring history includes two pairs of visits from the same day (28-Feb-1996 and 17-May-2001), measurements over a 24 -hour cycle (starting 24-Jun-2014), and multiple visits per year from 2000 through 2003.

The slabs within section 370208 exhibit a modest level of upward curl. In early morning or late evening visits, the length and severity of ALR increased because of an increase in the prevailing levels of upward curl. The increase in upward curl did not introduce new ALR, but it increased the range and severity of the existing ALR.

Figure 387. Graph. Total ALR length of section 370208 for the right wheel path.

Source: FHWA.
Figure 388. Graph. ER of section 370208 for the right wheel path.
Figure 389 through Figure 391 characterize the long-term trend in ALR for the right wheel path of section 200201 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. Three ALRs exist within this section early in its life. Inspection of the profiles showed that ALRs were caused by a slope break between an area of decreasing elevation and a flat area at 170 ft , two narrow bumps in the range from 285 to 300 ft , and a slope break between an area of decreasing elevation and a flat area at 430 ft .

ALR length and ER increased unsteadily throughout the life of section 200201. Two distressed slabs with faulting caused ALRs in the last 50 ft of the section. Slabs in this area were replaced in 1995. Replacement slabs were not flush with the surrounding pavement and cracked transversely. The replacement slabs grew progressively rough until they were replaced in June 2002. (Note the corresponding growth and subsequent reduction in ER in Figure 391.)

The new replacement slabs also caused ALRs. Later in the monitoring history of section 200201, ALRs appear in the right wheel path at distressed joints and at the locations of the joint-repair patches used to address the distress.

Most slabs within section 200201 were curled downward during monitoring visits starting at 7.55 years of age, which caused an increase in ALR length for the midafternoon visits on 06-May-2014 and 05-May-2014 relative to the early morning visits on 06-May-2014. The change in ER for the same visit was proportionately smaller than the change in ALR length because the increased downward curl during the midafternoon visits caused additional ALRs to appear with roughness slightly above the $125-\mathrm{inch} / \mathrm{mi}$ threshold.

Figure 391. Graph. ER of section 200201 for the right wheel path.

Figure 392 through Figure 394 characterize the long-term trend in ALR for the right wheel path of section 200205 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. This section included very little localized roughness early in its life, a somewhat steady increase over the first 12 years, then a more rapid increase after the first 12 years. A single slab with an elevation above the surrounding profile caused the largest ALR in the first 10 years of the history of section 200205.

A long-term increase in downward slab curl contributed to an increase in ALR in the second half of the monitoring history of section 200205. Distress at several joints and roughness at jointrepair patches placed in 2008, 2010, 2011, and 2014 contributed to an increase in ALR, including severe localized roughness in the right wheel path at a joint at 238 ft . Joint distress and joint-repair patches contributed to ER more than downward curl.

Figure 395 through Figure 397 characterize the long-term trend in ALR for the right wheel path of section 390209 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. This section included no ALR in the first monitoring visit and a modest increase in ALR length and ER in the first 10 years. The two ALRs in the first 10 years appeared in the presence of longwavelength roughness (i.e., long dips that include areas with rapid changes in slope). However, the roughness in these locations did not violate the $125-\mathrm{inch} / \mathrm{mi}$ threshold until short-wavelength roughness (i.e., faulting at joints and midslab cracks) appears. Roughness at distressed joints, faulted midslab cracks, and joint-repair patches caused the large increase in ALR length and ER starting at an age of 11.81 years.

Figure 398 through Figure 400 characterize the long-term trend in ALR for the right wheel path of section 200209 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. Two ALRs of low severity appeared in this section throughout its monitoring history. Each ALR appeared at the trailing end of a slab with a larger level of downward curl than the surrounding slabs. Researchers are not clear if structural behavior and environmental conditions caused the downward curling at these slabs or if construction defects caused roughness to appear in the shape of downward curling in these locations.

Figure 399. Graph. Total ALR length of section 200209 for the right wheel path.

Source: FHWA.
Figure 400. Graph. ER of section 200209 for the right wheel path.

Figure 401 through Figure 403 characterize the long-term trend in ALRs for the right wheel path of section 370260 using a base length of 25 ft and a roughness threshold of 125 inches $/ \mathrm{mi}$. Two ALRs appeared early in the life of this section with length and severity that remained stable throughout the monitoring period. A narrow dip at 6 ft caused the ALR at the start of the section. This dip was not severe, and the peak value of the roughness profile was typically 130 to 135 inches $/ \mathrm{mi}$. A bump that is more than 0.25 inches high from 310 to 318 ft from the start of the section caused the other ALR. This feature consistently caused peaks in the roughness profile above 200 inches $/ \mathrm{mi}$, and it contributed heavily to ER as a result.

Source: FHWA.
Figure 401. Graph. ALR map of section 370260 for the right wheel path.
Two ALRs appear early in the life of this section that increase in length and severity over the first 8 years, then remain stable for the rest of the monitoring period. The specific source of roughness from 170 to 230 ft is less clear although distress surveys show transverse cracks and joint distress. One ALR appears starting 4.35 years into the life of this section and remains
throughout the rest of the monitoring period. Roughness at this feature, however, is barely enough to violate the $125-\mathrm{inch} / \mathrm{mi}$ threshold.

## ALR REPEATABILITY

This section presents examples of ALR repeatability using profile measurements collected for the LTPP program. For most profile-monitoring visits, five repeat passes were selected for analysis from a larger set based on agreement in profile features that affect the IRI. Profiles from a specific section were aligned longitudinally over the monitoring history. The alignment process included longitudinal offset adjustment and application of a scale factor to the longitudinal distance interval to improve alignment over the entire length of the section. As such, disagreement within a set of repeat profile measurements corresponds to vertical measurement variations.

Table 70 through

Table 77 present relevant summary statistics for the eight sample sections discussed in the LongTerm Changes section. Repeatability is examined for total ALR length, ER, and ALR placement. The tables list the average IRI, average ALR length, and average ER for each profilemeasurement visit. The tables also list the SD of each quantity. The values in the tables are based on five passes per visit except for some visits in 2014 collected for the study of diurnal changes.

ALR length and ER vary more than overall IRI relative to their average values (i.e., the SD of ALR length and ER is greater relative to their average values than overall IRI), which is particularly true when the length and severity of ALR is low or when ALRs appear in some repeat passes. Variations in ALR length and ER are consistent with the observation by Sayers that when using a short base length, the detail within a roughness profile is more difficult to reproduce than the overall IRI. ${ }^{(106)}$

## Table 70 through

Table 77 list the ALR length common to all repeat passes within a given visit. The common length is the ALR length within a test section in which ALR was registered in every pass. Table 70 lists a value of $\mathbf{0 . 0} \mathbf{f t}$ for the first visit to section $\mathbf{0 4 0 2 2 3}$. The ALR map in Figure 380 shows that ALR appeared approximately 170 ft from the start of the section. However, the ALR only appeared in four of the five passes. In contrast, ALR appeared in all five passes in the fourth visit, with 8.2 ft of mutual overlap. Figure 380, Figure 383, Figure 386, Figure 389, Figure 392, Figure 395, Figure 398, and Figure 401 show ALR maps that correspond to the "common ALR length (ft)" columns in Table 70 through

Table 77. Typically, ALR with higher severity (i.e., greater ER) registered ALR length more consistently than ALR with peak values barely above the threshold value.

Table 70. ALR repeatability of section 040223 for the right wheel path at $\mathbf{1 2 5}$ inches $/ \mathbf{m i}$.
