Abstract

This report compares pavement profile data collected by four Profilometers^M used by SHRP's Long Term Pavement Performance Program (LTPP). Three of the Profilometers were identical; the sensors of the fourth were closer together. The purpose of the comparison is to determine if the Profilometers can collect repeatable data with respect to each other as well as individually at a given site, and whether they are collecting accurate data (determined by comparing the International Roughness Index computed from Profilometer data with that computed from Dipstick^M data).

1. INTRODUCTION

The Long Term Pavement Performance Program (LTPP) is one of four major technical research areas of the Strategic Highway Research Program (SHRP). As part of the LTPP study, pavement profile data are being collected at approximately 800 GPS and 100 SPS sites in the United States and Canada (1). The profile data are collected by regional contractors from the four regions: North Central, Western, North Atlantic and Southern. Each region employs its own Profilometer to collect data within the region. The four Profilometers that are being used have been manufactured by K.J. Law Engineers. Three of these Profilometers are identical. They were purchased by SHRP and then released to the regional contractors. The fourth Profilometer which belongs to the FHWA is on loan to SHRP. Although this Profilometer contains the same electro-mechanical equipment as the other Profilometers, the distance between the sensors in this unit is 54 in., while that of the other Profilometers is 66 in.(1). This Profilometer with the shorter distance between the sensors is being used by the North Central region. The Profilometers collect both the left and the right wheelpath profiles. This profile data is used to compute the International Roughness Index (IRI) of each wheelpath. Other statistical summarizes such as RMSVA, slope variance, etc. can also be computed using the profile measurements.

A comparative study between the Profilometers from the four SHRP regions was conducted in Ann Arbor, Michigan from June 3 to 7, 1991. The objectives of this Profilometer comparison are described in the next section.

2. OBJECTIVES

The following were the main objectives of the Profilometer comparison study.

- 1. Determine if the Profilometers can collect repeatable data with respect to each other.
- 2. Determine if repeatable data can be obtained by each Profilometer at a given site.
- 3. Determine if accurate data are being collected by the Profilometers, by comparing the IRI computed from Profilometer data with IRI computed from Dipstick data.

3. DESIGN OF EXPERIMENT

Several factors were identified as having a potential influence on the measurements collected by the Profilometers. Theses factors include: Profilometer used, speed of testing, surface type and level of roughness. The experimental plan selected for this study is shown in Fig. 3.1. In order to evaluate the influence of each factor the IRI index was used to summarize the measured profiles.

As shown in Fig. 3.1 eight pavement sections were used in this study. Four of the pavement sections were asphalt concrete while the other four were portland cement concrete. For each pavement type two levels of roughness were considered. A pavement was categorized as smooth if the IRI was less than 125 in./mile and as medium if the IRI was between 125 and 300 in./mile. Thus, for each pavement type, two of the selected pavements fell into the smooth category while the other two fell into the medium roughness category. At each section, each Profilometer tested at 40 and 50 MPH.

4. SELECTION OF SECTIONS AND DATA COLLECTION

4.1 Selection of Sections

The sections included in the Profilometer comparison study were selected such that they were similar to typical GPS sections. The following guidelines were followed in selecting the test sections (1).

- 1. The test section should be 500 ft long with similar profile characteristics throughout the 500 ft length as well as immediately before and after the test section.
- 2. The cross profile in the test section should be as uniform as possible and sites with changing cross profiles, bumps or aberrations should be avoided.
- 3. The test section should not be located on a horizontal curve greater than 3 degrees or on a vertical grade exceeding 4%.
- 4. The test section should not include any intersections.
- 5. The posted speed limit at the location must be at least 50 MPH.
- 6. The pavement reflectivity should be uniform throughout the test section to avoid lost lock situations.

Information regarding location, surface type and roughness level are presented in Table 4.1 for each section.

Table 4.1 Sections for Comparative Testing

4.2 Profilometer Data Collection

Every Profilometer was scheduled to test one asphalt and one concrete section per day. The concrete pavements were tested in the afternoon to minimize the effects of slab curling. The Profilometers were to test the sites according to the schedule shown in Table 4.2. This schedule was set up using a random number generator for the order of the Profilometers and the sites to be tested each day.

The guidelines given in the SHRP-LTPP manual for Profile Measurements (3) were generally followed when collecting profile data. However, for the comparative tests the left wheelpath was marked at each site. The drivers followed this wheelpath so that each Profilometer would collect similar data. The sites were first tested at 50 MPH and thereafter at 40 MPH. Each Profilometer was scheduled to perform six runs at the two speeds for a total of 12 runs per site. Additional runs were made if the operator believed that conditions occurred that would influence the run (i.e. side sway due to passing trucks). Also, additional runs were required if lost lock or saturation was detected during a run. However, the maximum number of runs at section was limited to nine. If situations causing lost lock or saturation could not be altered, the site was retested another day. Due to equipment problems or problems due to saturation spikes, some scheduled tests could not be performed. Any site that could not be tested on a scheduled day was tested on June 7th. The dates on which the Profilometers actually performed testing are shown in Table 4.3. Table 4.4 shows the number of runs performed by each Profilometer at each section at the two test speeds.

4.3 Dipstick Data Collection

Dipstick measurements were made on the left and right wheelpaths at all sections during field layout of the section. The procedure outlined in SHRP-LTPP manual for Dipstick Measurements (4) was followed in collecting the data. In each wheelpath, a forward and a return run was conducted using the Dipstick. The closing error specified in the SHRP manual for the Dipstick for a forward and a return distance of 500 ft (total of 1,000 ft) is 3 in. The closing error was within this allowable value at all sites.

5. COMPARISON BETWEEN PROFILOMETERS

5.1 Computed IRI

Figure 5.1 shows the experimental plan for the Profilometer comparison experiment with the section numbers that correspond to the different surface types and roughness levels (see Table 4.1). The number of replicates obtained for each cell of the experimental plan shown in Fig. 5.1 corresponds to the number of Profilometer runs shown in Table 4.4. The number of replicates in each cell would therefore vary from 6 to 9. During each run, the Profilometer collects profile data on the left and right wheelpaths. This profile data was input to the Profscan program (5) to obtain IRIs for the left and right wheelpaths. The combined effect of the left and right wheelpaths can be denoted by a both wheelpath IRI, which is the average of the left and right wheelpath IRI. Figure 5.2 shows the variation of left wheelpath IRI of Site 1 for all Profilometer runs for a testing speed of 40 MPH. Graphs showing the variation of left and right wheelpath IRI for all Profilometer runs at all sections are given separately for test speeds of 40 and 50 MPH in Appendix A. These graphs show that at some sites the IRI obtained from the different runs of the same Profilometer are not uniform.

As each Profilometer crew was instructed to obtain six good runs, only six runs in each cell of the experimental plan shown in Fig. 5.1 were selected for analysis. If only six runs were available in a cell, then all the runs were included in the analysis. In cases where more than six runs were available, in many instances the operators had not specifically commented on the runs that were bad. Therefore, the six best runs could not be selected from multiple runs based solely on the operators comments. Therefore, the criteria used to select the six best runs for analysis was to select the six runs that had the least standard deviation. It was noted that runs that were specifically labeled as bad by the operators were rejected when the above criteria was applied.

The left and right wheelpath IRI of all the runs that were selected for analysis are given in Appendix B. The average left wheelpath, right wheelpath and both wheelpath IRI computed from the six Profilometer runs selected for analysis at all sections for both test speeds is shown in Tables 5.1, 5.2 and 5.3 respectively.

Figures 5.3 and 5.4 show the relationship between the left and right wheelpath IRI for the asphalt and concrete pavements respectively. All Profilometer runs selected for analysis at both test speeds (192 runs each for asphalt and concrete pavements) are plotted in each figure. In each figure a cluster of points correspond to a section and the results from 48 Profilometer runs (four Profilometers, six runs each and two test speeds) are

Page -16-

represented at each section. The numbers adjacent to the cluster of points refer to the section numbers associated with each set of points. Figure 5.3 shows that the IRI of right wheelpath at Site 2 is much higher than the left wheelpath.

5.2 Acceptance Criteria

The Profscan program (5) is used to determine if the variance between runs made at a section is acceptable. In order for the runs to be acceptable, the following criteria must be met.

- 1. The IRI of at least three runs should be within 1% of the mean of all selected runs.
- 2. The standard deviation of all the selected runs should not exceed 3% of the mean (Coefficient of Variation $\leq =3\%$).

The user can select the runs to be used with thhe Profscan program out of all available runs. Therefore, if the operator knows that a particular run is bad, it can be omitted when the runs are analyzed with Profscan. Currently Profscan uses the both wheelpath IRI to determine the acceptability of runs.

All six replicate runs selected for analysis for each test situation in Fig. 5.1 were processed with the Profscan program to determine if the criteria were met. Since all Profilometers were aligned with the left wheelpath, an analysis was performed to determine the acceptability of runs at a site applying the criteria to the left wheelpath IRI. The summary statistics for the left wheelpath IRI (mean and standard deviation) for each series of runs by a Profilometer at a site for a specified speed were used to select the acceptable runs. Table 5.4 shows the number of runs for each test situation that met the 1% of the mean criteria which was applied to the left wheelpath IRI. The standard deviation and the 3% of the mean values of the left wheelpath IRI for each test situation are shown in Table 5.5. The analysis of the left wheelpath IRI showed that the 1% of mean criteria was satisfied by 58% of the test situations. This analysis showed that the 1% of the mean criteria in Profscan is more rigid than the standard deviation criteria. In this analysis it was noted that sections which failed the standard deviation criteria also failed the criteria on the mean.

The number of runs meeting the 1% of the mean criteria when the both wheelpath IRI is considered are shown in Table 5.6. When the 1% criteria was applied for the both wheelpath IRI, 73\% of the test situations shown in Fig. 5.1 satisfied the criteria.

٠.

:

Therefore, using the both wheelpath IRI as opposed to the left wheelpath IRI caused more test situations to meet the 1% criteria.

The percent difference from the mean IRI for each Profilometer run in the experiment was calculated using the following formula.

$$P = \frac{|(Y - R)|}{Y} \quad X \ 100$$

where, Y = Average IRI for a given test situation (average IRI of a cell in Fig. 5.1), R = IRI from a run corresponding to that test situation, and P = Percent difference from mean IRI for the run.

As there are six runs in each cell of Fig. 5.1, the percent difference from mean can be calculated for 384 runs. The relationship between the percent difference from the mean and the average IRI for each test situation are shown for the left and both wheelpath IRI in Figs. 5.5 and 5.6 respectively. These figures show that the percent difference from the mean IRI for the both wheelpath has less scatter as compared to the left wheelpath. In addition, these figures show that the percent difference from the mean IRI of a run is not dependent on the magnitude of IRI at that location.

The percentage of runs that fall into the different ranges of percent difference from mean for the left and both wheelpaths are shown in Table 5.7. Table 5.8 shows the percentage of runs that fall below a specified percent difference from the mean (calculated from the data given in Table 5.7). The percentage from mean IRI within which 95% of the runs fell were 4.3% and 2.6% for the left wheelpath and both wheelpaths, respectively.

5.3 Analysis of Variance

The effect of the different levels of the factors Profilometer, speed, roughness and surface type on IRI can be determined by conducting an Analysis of Variance (ANOVA) on the data collected from the experimental plan shown in Fig. 5.1. Only the six best runs selected as described in Section 5.1 were used in ANOVA. The experimental design shown in Fig. 5.1 corresponds to a nested-factorial design (6,7).

A nested design is one in which the level of one factor is similar but not identical for different levels of another factor. If a nested design contains another factor or factors which have the same level across other factors, this mixture of nesting and factorial structure is called a nested factorial design (6,7). For example, in Fig. 5.1 the sections that appear under the roughness level smooth (1 and 4) and the sections that appear under

roughness level medium (2 and 3) are different. Thus, the factor section is nested within the factor roughness. However, for example, all levels of factor speed appear with all levels of factor Profilometer. Therefore, it can be seen that this design contains both nested and factorial factors.

The statistical model used to analyze the experiment and the ANOVA table with the expected mean squares is given in Appendix C. The ANOVA was carried out using the SPSS program (8). The ANOVA was carried out for the Profilometer combinations shown in Table 5.9.

Case	Profilometer Combination				
1	NC WE NA SO				
2 3	NC WE NA NC WE SO				
4	NC NA SO				
NC - North Central Region	WE - Western Region	<u> </u>			
NA - North Atlantic Region	SO - Southern Region				

Table 5.9. Profilometer Combinations Used for ANOVA

For each Profilometer combination an ANOVA was carried out separately on the left wheelpath, right wheelpath and both wheelpath IRI. An alpha value of 0.05 was used to determine significance in all analyses.

5.3.1 ANOVA - Left Wheelpath IRI

As all Profilometers were aligned to the left wheelpath, the IRI of this wheelpath can be used to compare the Profilometers. Table 5.10 shows the results of ANOVA for the left wheelpath. The computer outputs of the ANOVA are given in Appendix D. The factors that are significant at an alpha value of 0.05 are marked in Table 5.10. The only case where the Profilometers were not significant was when the North Central, Western and North Atlantic Profilometers were grouped together. In all cases where the Southern Profilometer was present, the factor Profilometer was significant. As expected roughness was significant for all cases. Speed of testing was not significant for all cases. The mean IRI of all runs in all sections for both speeds for North Central, Western, North Atlantic and Southern Profilometers are 125.4, 124.2, 125.3 and 138.9 in/mile respectively. These values clearly show that the mean IRI of the Southern Profilometer is higher than the other Profilometers and support the findings of the statistical analysis.

Table 5.10 ANOVA Results for the Left Wheelpath

-- -- ----

:

.

5.3.2 ANOVA - Right Wheelpath IRI

Table 5.11 shows the results of the ANOVA for the right wheelpath. The computer outputs of the ANOVA are given in Appendix E. As seen in Table 5.11 the factor Profilometer was not significant for three Profilometer combinations. The North Central unit was in all three combinations in which the Profilometers were not significant in spite of it having a different sensor spacing. For the case where the Southern, Western and North Atlantic Profilometers which have the same sensor spacings were grouped together, the factor Profilometer was significant. For the first two Profilometer combinations (see Table 5.11), the speed of testing was significant.

5.3.3 ANOVA for Both Wheelpath IRI

The results of ANOVA for both wheelpath IRI is given in Table 5.12. The computer outputs for the analysis is given in Appendix F. The factor Profilometer was not significant only for the Profilometer combination North Central, Western and North Atlantic. The speed of testing was not significant for any combination. However, as seen from Table 5.12 some interactions were significant.

6. REPEATABILITY OF PROFILOMETERS

The Coefficient of Variation which is the ratio between the standard deviation and the mean of a data set expressed as a percentage can be used to judge variability in data. The Coefficient of Variation of left wheelpath, right wheelpath and both wheelpath IRI computed using the six Profilometer runs selected for analysis for each test condition is given in Tables 6.1 - 6.3. These values are shown graphically in Figs. 6.1 to 6.6. The Profscan program (5) sets a 3% limit on the coefficient of variation through its standard deviation criteria (standard deviation of a set of runs should not exceed 3% of the mean for data acceptability). When the coefficients of variation for the left wheelpath IRI (given in Table 6.1) were analyzed, it was seen that in 90% of the cases the coefficients of variation were within this 3% criteria. A similar analysis of the coefficients of variation of the IRIs of the right wheelpath and the both wheelpath (given in Tables 6.2 and 6.3 respectively) showed that the 3% criteria was satisfied in 90% of the test situations for the right wheelpath and 97% of the test situations for the both wheelpath.

Plots of coefficient of variation with the associated average IRI for the left, right and both wheelpaths are given in Figs. 6.7, 6.8 and 6.9. The coefficients of variation for

the left and right wheelpaths obtained for different test conditions indicate that the repeatability of all Profilometers in the left and right wheelpaths were satisfactory.

Table 6.4 presents the average coefficients of variation of left, right and both wheelpath IRI for the asphalt and concrete pavements. For example, a coefficient of variation given in a cell for asphalt pavements represents the average coefficient of variation of the four asphalt pavements considered in this study. There was no noticeable variation in repeatability of the Profilometers with respect to pavement type (asphalt and concrete) and the two test speeds (40 and 50 MPH) as seen from the coefficients of variation.

7. COMPARISON BETWEEN PROFILOMETER AND DIPSTICK IRI

Dipstick measurements were made on the left and right wheelpaths at all sites. The Dipstick measures the difference in elevation between two points at 12 in. intervals. Figure 7.1 shows the data obtained from the Dipstick over a distance of 100 ft. In this figure the vertical distance between two adjacent points represents the difference in elevation between the two points. A running sum of the Dipstick readings can be used to generate an elevation profile of the site. Figure 7.2 shows the elevation profile obtained from the Dipstick measurements shown in Fig. 7.1.

The computer program given in the World Bank Technical Paper 46 (9) was used to compute the IRI from the Dipstick data. The program that was used is given in Appendix G. The factors and coefficients appropriate for the sampling interval of the Dipstick are used in this program. The Dipstick data is input to the program through a data file. The IRI computed for the forward and return runs of the Dipstick on each wheelpath together with the mean IRI obtained by averaging the forward and return runs are shown in Table 7.1.

The mean IRI for each Profilometer computed from the six runs at 50 MPH, and the mean Dipstick IRI computed from the forward and return runs are shown in Table 7.2. The ratios between the IRI obtained from the Profilometer and Dipstick are shown in Table 7.3. For the left wheelpath, this ratio varies between 0.93-1.19 for North Central, 0.86-1.08 for Western, 0.85-1.19 for North Atlantic and 1.00-1.17 for Southern. The relationship between the IRI computed from the Profilometer data at 50 MPH and Dipstick data for the four Profilometers are shown graphically in Figs. 7.3 to 7.10.

ANOVA was used to determine if there was a statistical difference between the left wheelpath IRI computed from the profile data collected by the North Central, Western and

North Atlantic Profilometers and the Dipstick. The left wheelpath IRI was selected for comparison as all Profilometers were aligned to this wheelpath. The Southern Profilometer was not included in this analysis as it was seen in Section 5 that the left wheelpath IRI computed from this unit was different than the other three Profilometers. The factors considered for this ANOVA were device (the three Profilometers and the Dipstick) and sections (eight sections given in Table 4.1). As the factor device is a fixed factor and the factor sections is a random factor, a mixed model has to be analyzed. For each section all Profilometers had six replicates (six runs) while the Dipstick had only two replicates (a forward run and a return run). This caused the design to be unbalanced. To avoid complications caused by unbalanced mixed models this problem was analyzed as a balanced factorial design. For each Profilometer two runs were selected out of the six available runs using a random number generator, thus giving a balanced design. The results of the ANOVA showed that the factor device was not significant. The results of the ANOVA are given in Appendix H.

The mean IRIs from the Dipstick and the Southern Profilometer were compared using a paired T-test. Eight data sets corresponding to the eight test sites were available. The mean IRI for the Profilometer was taken as the mean IRI obtained from six runs, while for the Dipstick the mean IRI correspond to the mean of the forward and return runs. At a alpha value of 0.05 the mean values for the left wheelpath IRI were not equal for the two devices.

Table 7.4 gives the results of a regression analysis carried out between the IRI of each Profilometer and the Dipstick for each wheelpath. Though very high coefficients of correlations (\mathbb{R}^2) were obtained in all cases, the magnitude of the standard error of estimate should be considered when using these equations.

8. SUBSEQUENT COMPARISON

After the Profilometer comparison study was completed, it was found that there was a malfunction in a computer board related to the left sensor in the Southern Region Profilometer. This could have resulted in erroneous readings for the left sensor during testing. After this problem was corrected, another series of comparative testing at all the eight sections were performed between the Southern and North Central Region Profilometers in September 1991. Unlike the June comparative test, the left wheelpath was not marked at the test sections for this study. Therefore, the Profilometer drivers had to judge the position of the left wheelpath. After the IRIs were computed for all runs, as

,

before the six best runs were selected for analysis based on the standard deviation. The IRI computed for the September testing for North Central and Southern Profilometers is given in Appendix I.

First an ANOVA was conducted using the IRI obtained by the North Central Profilometer in June (during comparative testing) and September to determine if there was a difference in the IRI with respect to time. The design that was used for the ANOVA was the same as that shown in Fig. 5.1 except that the factor Profilometer was replaced by the factor time, which had two levels (June and September). ANOVA was carried out separately for the left wheelpath and right wheelpath IRI. The ANOVA of the left wheelpath IRI indicated that the IRI from the two time periods were not different. However, the analysis of the right wheelpath IRI showed that the IRI for the two time periods were different. As the left wheelpath was not marked during the September test, the path followed by the Profilometer at a section may not be the exact path followed during the June test. The right wheelpath IRI, especially in asphalt pavements may have been affected by such a situation due to transverse variability in pavement profile near the pavement edge. This could have caused the result obtained in the ANOVA for the right wheelpath. The details of the ANOVA are given in Appendix I.

Thereafter, an ANOVA was performed between the IRI obtained from the North Central and Southern Profilometers from the September comparative study. The Southern Profilometer did not test site 4 due to equipment problems. In addition the data obtained for sites 2 and 3 were contaminated by radar spikes and could not be used. Therefore, only five sections were available for this comparison. Due to this reason the earlier design (Fig. 5.1) could not be used and the design shown in Fig. 8.1 was used to conduct the ANOVA. In this design the main factors are Profilometers, speed and sections. The Southern region data used for this analysis is given in Appendix I. The ANOVA for left as well as right wheelpaths showed that the factor Profilometer was significant. The computer outputs for this analysis are given in Appendix I.

The mean IRI of the sections computed from North Central and Southern Profilometer data from the September comparison are given in Table 8.1. The values in this table show that there is a difference in IRI for the left as well as the right wheelpaths for the two Profilometers. However, the difference between the computed IRIs for the two Profilometers in the left wheelpath were much greater than that for the right wheelpath (see Table 8.1). The differences in the left wheelpath IRI are much greater than a difference that is expected due to variation in wheelpath between the two Profilometers. Although ANOVA showed that the IRI of profile data collected by the two Profilometers were different in the right wheelpath, this difference may be due to variations in the Fig. 8.1. Design used to analyze North Central and Southern Region Profilometer Comparison

wheelpaths measured by the two devices. The magnitudes of the differences in the IRI between the two devices in the right wheelpath (see Table 8.1) tends to support this. This comparison showed that the profiles measured by the Southern Profilometer in the left wheelpath were still different from the profiles measured by the North Central Profilometer. The replacement of the computer board in the Southern Profilometers has not corrected the problem with the left sensor.

9. COMMENTS ON TEST PROGRAM AND ANALYSIS

- 1. During comparative testing the Profilometer operators used the both wheelpath IRI to determine if a series of Profilometer runs at a site satisfied the Profscan criteria.
- 2. No adjustments were made to eliminate spikes in the profile data collected by the Profilometers. In the Profscan program a spike threshold value of 0.1 in. was used. When Profscan computes IRI it indicates possible spikes in a run based on this criteria. In most instances where spikes were present in Profilometer runs at a section, the variability of IRI between the runs was small. It is most likely in such cases the spikes were the result of the anomalies in the pavement. However, in a few instances the Profilometer runs at a sections which contained spikes had large variability of IRI between runs. In such cases the spikes were obviously due to some external causes. Such runs were not included in the analysis as they were eliminated when the six runs for the analysis were selected based on the standard deviation criteria.
- 3. No filtering was performed on the Dipstick data before computing the IRI.
- 4. The surface type (asphalt or concrete) was used as a factor in ANOVA. In order to determine if there is a difference in readings taken by the Profilometers on an asphalt surface as opposed to a concrete surface, asphalt and concrete sections that have identical IRIs are needed. In this experiment there was no correspondence between the levels of IRIs of the two smooth asphalt sections with the two smooth concrete sections. This also holds true for the sections with medium roughness. Therefore, in the ANOVA the factor surface type merely indicates whether there is a difference in IRI between the asphalt and concrete sections. As the mean IRI of the asphalt and concrete sections used in this experiment are very close to each other, the factor surface type does not become significant.

10. CONCLUSIONS

- 1. When the IRIs of the left wheelpath were analyzed, the criteria that at least three runs should be within 1% of the mean was met by only 58% of the test situations. However, the criteria that the standard deviation of the runs should be within 3% of the mean was met by over 90% of the test situations. Even in this controlled experiment where the left wheelpath was marked, the 1% criteria on the mean was difficult to achieve in many situations when the left wheelpath IRI was considered. However, when the both wheelpath IRI was considered, the 1% criteria was met by 73% of test situations. It was seen that the acceptance of the 1% of the mean criteria at a site based on the both wheelpath IRI does not automatically ensure that the criteria is met by the individual wheelpath IRIs.
- 2. When the left wheelpath IRIs were analyzed, 95% of all runs were within 4.3% of the average left wheelpath IRI associated with the runs. When the both wheelpath IRI was considered 95% of all runs were within 2.6% of the both wheelpath IRI associated with the runs. This shows when a set of Profilometer runs are considered, a criteria based on the both wheelpath IRI is easier to achieve than a criteria based on the left wheelpath IRI.
- 3. The ANOVA of the left wheelpath IRIs shows that the profile data collected by the left sensor of the Southern Region Profilometer was different than that of the other three units. ANOVA showed that the left wheelpath IRI computed from the data collected by the North Central, Western and the North Atlantic Region Profilometers were similar.
- 4. In the right wheelpath, ANOVA indicated that the profile data collected by the Profilometer combinations of: (a) North Central, Western and North Atlantic (b) North Central, Western and Southern (c) North Central, North Atlantic and Southern were similar. Although the right wheelpath of the North Central Profilometer does not follow the same wheelpath as the other units, all three cases in which the Profilometers were not significant in the ANOVA involved this unit. However, the ANOVA of the right wheelpath showed that at least one Profilometer was different from the others in the Profilometer combination of Western, North Atlantic and Southern Region, though these units have similar sensor spacings.
- 5. The results from ANOVA of the left wheelpath IRIs showed that the speed of testing was not significant. For the right wheelpath the speed of testing was a

significant factor for two Profilometer combinations out of a total of five combinations that were analyzed.

- 6. All Profilometers showed excellent repeatability in both wheelpaths, except at a few sections which had spikes in the profile data. It was observed that the repeatability of the Profilometers was not affected by surface type (asphalt vs concrete), the level of roughness (smooth vs medium) or the two speeds selected for testing (40 MPH vs 50 MPH).
- 7. A statistical analysis indicated that the IRI computed for the left wheelpath from the data collected by the Profilometers of the North Central, Western and North Atlantic regions as well as the Dipstick were similar. This indicates that the three SHRP Profilometers from the North Central, Western and North Atlantic Regions are collecting accurate data in the left wheelpath.

11. RECOMMENDATIONS

- The criteria used in the Profscan program (that three IRI values should be within 1% of the mean) was found to be difficult to achieve in many situations in this controlled experiment where the wheelpaths were marked. Thus, this criteria would be harder to achieve during routine testing where the wheelpaths are not marked. It is recommended that this criteria be relaxed.
- 2. ANOVA showed that the left wheelpath IRI of the Southern Profilometer was different from the other three Profilometers. The overall mean of the left wheelpath IRI obtained from all runs performed at all sections were 125.4, 124.2, 125.3 and 138.9 in/mile for North Central, Western, North Atlantic and Southern Profilometers respectively. These numbers as well as the figures in Appendix A show that the left wheelpath IRI of the Southern unit is significantly higher than the other units. However, the Southern Profilometer was as repeatable as the other Profilometers.

In order to obtain comparable IRIs, the IRIs obtained from the Southern unit need to be adjusted. Appendix J gives the details of a comparison of the mean left wheelpath IRI of the Southern and the North Central units for both the June and September studies. This comparison shows that a relationship between the IRIs of the Southern and North Central units can be developed. Therefore, such a relationship can be used to correct the left wheelpath IRIs of the Southern Profilometer.
ANOVA of the right wheelpath IRI did not indicate that the right wheelpath IRI of the Southern unit was different from the other units. The overall mean IRIs for the right wheelpath were 138, 136.5, 142 and 138 in./mile for North Central, Western, North Atlantic and Southern units. These numbers as well as the figures in Appendix A do not show any evidence that there is a significant difference between the right wheelpath IRIs of the Southern unit and the other units. Therefore, no adjustments are recommended for the right wheelpath IRIs obtained from the Southern Region Profilometer.

It is recommended that a comparative study be performed between the Southern unit and another unit from any region on a series of sections which will encompass the range of roughness encountered during routine testing to develop correction factors (as outlined in Appendix J) for the left wheelpath IRI of the Southern Profilometer.

3. It is recommended that a Profilometer comparison study similar to this study at Ann Arbor be conducted annually. Results of such a study will provide a check on the accuracy of all Profilometers. In future studies it is recommended that testing be performed only at 50 MPH, as this study showed that there was no difference in IRI for test speeds of 40 and 50 MPH.

LEFT AND RIGHT WHEELPATH IRI OF ALL RUNS SELECTED FOR ANALYSIS

The data obtained from the profilometer comparative study is given in tabular form in this appendix. A description of each column of this table is given below.

Column 1 - NO: Data set Number.

Column 2 - DEVICE: Profilometer. NC - North Central Region Profilometer, WE - Western Region Profilometer, NA - North Atlantic Region Profilometer, SO - Southern Region Profilometer.

Column 3 - ROUG: Roughness Level. 1 corresponds to a smooth pavement (IRI < 125 in/mile) while 2 corresponds to a pavement with medium roughness (IRI between 125 and 300 in/mile).

Column 4 - SURTYP: Surface Type. Surface type 1 is asphalt while surface type 2 is concrete.

Column 5 - SECNO: Section Number. Eight sections were used for the study.

Column 6 - SPEED: Speed of testing (either 40 or 50 mph).

Column 7 - RUN: Run Number (1 through 6).

Column 8 - LIRI: IRI (in/mile) of the left wheelpath obtained from PROFSCAN.

Column 9 - RIRI: IRI (in/mile) of the right wheelpath obtained from PROFSCAN.

Column 10 - BIRI: Both wheelpath IRI (in/mile). This is the average of the left and right wheelpath IRI's.

Column 11 - DISP: Displacement (mm/mile).

STATISTICAL MODEL AND ANOVA TABLE

The factors considered in this experiment together with the levels employed are given below.

•

.

FACTOR	LEVELS	EFFECT
SURFACE TYPE	Two 1. Asphalt Concrete 2. Portland Cement	Fixed
ROUGHNESS	Two 1. Smooth 2. Medium	Fixed
PROFILOMETER	Four 1. North Central Region 2. Western Region 3. North Atlantic Region 4. Southern Region	Fixed
SPEED	Two 1. 40 mph 2. 50 mph	Fixed
SECTIONS	Eight	Random

•

```
The statistical model employed for this study is described
by the following equation :
Y<sub>ijklm</sub> = PROF<sub>i</sub> + ROUGH<sub>j</sub> + SURTYP<sub>k</sub> + SEC(ROUGH,SURTYP)<sub>l(jk)</sub> +
SPEED<sub>m</sub> + ROUGH*SURTP<sub>jk</sub> + PROF*SURTYP<sub>ik</sub> + SURTYP*SPEED<sub>km</sub> +
PROF*ROUGH<sub>ij</sub> + ROUGH*SPEED<sub>jm</sub> + PROF*SEC(ROUGH,SURTYP)<sub>il(jk)</sub>
+ SEC*SPEED(ROUGH,SUYRTYP)<sub>lm(jk</sub>) + PROF*SPEED<sub>im</sub> +
PROF*ROUGH*SURTYP<sub>ijk</sub>+ ROUGH*SURTYP*SPEED<sub>jkm</sub> +
PROF*ROUGH*SURTYP<sub>ijk</sub>+ ROUGH*SURTYP*SPEED<sub>jkm</sub> +
PROF*SEC*SPEED(ROUGH,SURTP)<sub>ilm(jk</sub>) +
PROF*ROUGH*SURTYP*SPEED<sub>ijkm</sub> + ERROR
where,
PROF = Profilometer
ROUGH = Level of Roughness
SURTYP = Surface Type
```

```
SEC = Sections nested within surface type and roughness
```

SPEED = Speed of Testing

.

The Analysis of Variance (ANOVA) table for this model together with the expected mean squares is shown below.

FACTOR	MEAN SQUARES
PROF	$bcdfeF(P) + ef\sigma^2_{P,S} + \sigma^2$
ROUGH	$acdefF(R) + aef\sigma_{S}^{2} + \sigma^{2}$
SURTYP	$abdefF(T) + aef\sigma_{S}^{2} + \sigma_{S}^{2}$
SEC (ROUGH, SURTYP)	$aef\sigma^2_S + \sigma^2$
SPEED	$abcdefF(SP) + af\sigma^2_{S.SP}$
ROUGH*SURTYP	$adefF(R,T) + aef\sigma_{S}^{2} + \sigma^{2}$
PROF*SURTYP	$bdefF(P,T) + ef\sigma_{P,S}^2 + \sigma^2$
SURTYP*SPEED	$abdfF(T,SP) + af\sigma^2_{S,SP} + \sigma^2$
PROF*ROUGH	$cdefF(P,R) + ef\sigma^{2}_{P,S} + \sigma^{2}$
ROUGH*SPEED	$acdfF(R,SP) + af\sigma^2_{S,SP} + \sigma^2$
SEC*PROF (ROUGH, SURTYP)	$ef\sigma^2_{P,S} + \sigma^2$
SEC*SPEED(ROUGH, SURTYP)	$af\sigma^2 s, sP + \sigma^2$
PROF*SPEED	$bcdfF(P,SP) + f\sigma^2_{P,S,SP} + \sigma^2$
PROF*ROUGH*SURTYP	defF(P,R,T) + $ef\sigma^2_{P,S} + \sigma^2$
ROUGH*SURTYP*SPEED	$adfF(R,T,SP) + af\sigma^2_{S,SP} + \sigma^2$
PROF*SURTYP*SPEED	$bdfF(P,T,SP) + f\sigma^2_{P,S,SP} + \sigma^2$
PROF*ROUGH*SPEED	$cdfF(P,R,SP) + f\sigma^2_{P,S,SP} + \sigma^2$
PROF*SEC*SPEED (ROUGH,SURTYP)	$f\sigma^2_{P,S,SP} + \sigma^2$
SURTYP*ROUGH*PROF*SPEED	dfF(P,R,T,SP) + σ^2
Note :	
P = Profilometer a	= Levels for profilometers
$\mathbf{K} = \mathbf{K}$ and $\mathbf{K} = \mathbf{K}$ and $\mathbf{K} = \mathbf{K}$ and $\mathbf{K} = \mathbf{K}$	= Levels for surface type
S = Sections d	= Levels for sections
SP= Speed e	= Levels for speed

CORRECTION FACTORS FOR IRI OF SOUTHERN REGION PROFILOMETER

ANOVA indicated that the left wheelpath IRI of the Southern profilometer was different from the other three profilometers. A comparison was performed between the left wheelpath IRI of the Southern and North Central profilometers to see if there was a relationship between the IRI's. The mean IRI (in/mile) obtained for each site from the two profilometers from the June comparison study are given below.

Section	1	2	3	4	5	6	7	8
N. Central	72	211	149	63	169	166	121	58
Southern	82	230	157	59	199	180	130	62

In the comparative study performed in September, all sections could not be tested by the Southern profilometer. The table below gives the IRI's of the tested sections.

Section	1	5	6	7	8
N. Central	68	177	164	120	67
Southern	82	208	183	128	80

Figures J1 and J2 show the relationship between the left wheelpath IRI's from the Southern and North Central profilometers for the June and September comparisons respectively. These figures show that the IRI's from the Southern unit are higher than those from the North Central Fig. J1 MEAN LEFT WHEELPATH IRI FOR SOUTHERN AND N. CENTRAL PROFILOMETERS - JUNE COMPARISON

Fig. J2

Page -152-

unit. The only exception occurred during the June testing at a site that had a very low IRI.

The mean left wheelpath IRI's obtained form the June and September study were used to develop a regression equation relating the North Central and Southern profilometers. The results obtained are given next.

RESULTS FROM REGRESSION ANALYSIS

Study	Regression Equation	R ²	SEE
June	Y = 0.873X + 6.22	0.99	6.38
September	Y = 0.885X - 1.27	0.99	6.48
Note :		<u>,</u>	, <u></u> .
1. $Y = Left$ when $Y = Left$	elpath IRI of N. Central u	unit, $X = 1$	Left
2. R^2 - Coeffic	cient of determination		
3. SEE = Standa	ard error of estimate		

It should be noted that eight data sets were used for the equation developed from the June study, while only five data sets were available for the equation developed from the September study. A regression equation of the above form developed by a comparison study between the Southern unit and a profilometer from any of the other three regions can be used to correct the IRI's of the left wheelpath obtained from the Southern unit.
